Summary of recommendations

1. European Stroke Organisation (ESO) and European Academy of Neurology (EAN) Joint Guidelines on post-stroke cognitive impairment

   This guideline will be published in the European Stroke Journal.

2. Authors

3. Abstract

4. Summary table of recommendations

5. Plain Language Summary

6. Introduction

7. Methods

8. Results

   8.1 Monitored lifestyle-based interventions for the prevention of poststroke cognitive decline or dementia

   We cannot recommend monitored lifestyle interventions solely for the prevention of post-stroke cognitive decline or dementia.

   Quality of evidence: Very Low ⊕

   (This recommendation only relates to cognitive effects of lifestyle interventions)

   Consensus recommendation

   Lifestyle interventions, alone or in combination, should not be used solely for the prevention of post-stroke cognitive decline or dementia. Other benefits, such as a better physical or mental health or the prevention of future cardiovascular disease may warrant recommendations on lifestyle after stroke, but these were not the focus of this guideline.

   There is a need for further, adequately powered trials that assess the effect of monitored lifestyle interventions on cognitive decline following stroke.

   8.2 Monitored intensive management of vascular risk factors for the prevention of poststroke cognitive decline or dementia

   Blood pressure treatment

   We cannot recommend intensive treatment of blood pressure compared to usual care solely for the prevention of post-stroke cognitive decline and dementia.

   Quality of evidence: Very Low ⊕

   (This recommendation only relates to cognitive effects of blood pressure treatment)
Weak recommendation against
Antithrombotic therapy
We suggest against using dual antiplatelet therapy compared to single antiplatelet therapy for the prevention of cognitive decline or dementia following lacunar stroke.
Quality of evidence: Very Low ⊕
(This recommendation relates to cognitive effects of dual antiplatelet and is applicable to lacunar stroke only)

Statin treatment
We cannot recommend intensive statin treatment compared to usual care solely for the prevention of post-stroke cognitive decline or dementia.
Quality of evidence: Very Low ⊕
(This recommendation only relates to cognitive effects of statin treatment)

Consensus recommendation

Given the beneficial effects of vascular risk management on prevention of recurrent stroke and cardiovascular disease, comprehensive risk factor management including blood pressure reduction, antithrombotic and statin is warranted following stroke, even though the cognitive benefits are unclear.

Targets for stroke risk factor management are constantly evolving and approaches that were historically considered 'intensive' are now common practice and recommended in guidelines.

Future trials of secondary prevention in stroke should include cognitive outcome measures.

8.3 Monitored multicomponent interventions (lifestyle and pharmacological) for the prevention of poststroke cognitive decline or dementia
We cannot recommend multicomponent interventions (including medications and lifestyle interventions) solely for the prevention of post-stroke cognitive decline or dementia.
Quality of evidence: Very Low ⊕
(This recommendation only relates to the cognitive effects of multicomponent interventions)

Consensus recommendation

All but one of the writing group agreed that:
Monitored multicomponent interventions, cannot be recommended for the prevention of cognitive decline or dementia following stroke alone, but there are other potential health benefits associated with these lifestyle interventions, such as the prevention of future cardiovascular disease or recurrent stroke.

8.4 Cognitive training for the prevention of poststroke cognitive decline and dementia
There is continued uncertainty over the benefits and limitations of cognitive training for the prevention of cognitive decline and dementia in people living with stroke.
Quality of evidence: Very Low ⊕
Consensus recommendation

All but one of the writing group agreed that:

Cognitive training could be considered following stroke as part of a broader rehabilitation package. However, based on the current available literature, there is no evidence that cognitive training, as a single intervention, has a clinically meaningful or sustained benefit for prevention of cognitive decline or dementia following stroke.

8.5 Stopping pharmacological management of vascular risk factors (de-prescribing) for the prevention of poststroke cognitive decline and dementia

There is continued uncertainty over the benefits and risks of continuing treatment with antihypertensive or statin medications compared to withdrawal of these medications for cognitive or quality of life outcomes in people living with post-stroke dementia.

Quality of evidence: Very Low ⚫

Consensus recommendation

Given the beneficial effect on cardiovascular disease/stroke prevention and no clear signal of cognitive harm, pharmacological vascular risk factor management should be continued in patients with mild to moderate post-stroke dementia.

In people living with more advanced dementia and short life expectancy, where the potential harms and burden of treatment may be greater than any vascular protection, the benefits of continuing stroke secondary prevention medications are unclear.

Pragmatic trials of deprescribing medications are needed to guide treatment decisions in people living with advanced post-stroke dementia.

8.6 Routine cognitive screening for the prevention of poststroke cognitive decline or dementia

Due to a lack of relevant trials in patients with stroke, there is continued uncertainty over the benefits and risks of routine cognitive screening to improve stroke care.

Quality of evidence: Very Low ⚫

*(this recommendation applies only to routine screening of all patients presenting with stroke, and does not apply to clinician directed assessment)*

Consensus recommendation

Cognitive screening should be considered as part of the comprehensive assessment of stroke survivors.

However, there are insufficient data to make recommendations around the timing, the content or the potential benefits of cognitive screening to the patient, their care-givers, and to healthcare systems.

Further studies describing the effects of routine cognitive screening following stroke are required. These studies should include acute stroke settings, should record feasibility and acceptability, consider effects on care pathways, and describe care-giver outcomes and health economics.

8.7 Accuracy of Montreal Cognitive Assessment for contemporaneous diagnosis of post-stroke cognitive impairment or dementia
Weak recommendation

We suggest that in post-acute stroke settings, screening of cognition using the Montreal Cognitive Assessment (MoCA) is considered. MoCA should not be used as a substitute for comprehensive clinical assessment.

At the conventional threshold for test positivity, MoCA screening will detect most stroke survivors with important cognitive issues but at the cost of substantial false positives. We suggest that a revised (lower) threshold be considered for stroke populations.

Quality of evidence: Low ⊕⊕

Consensus recommendation

There are inherent limitations to the Montreal Cognitive Assessment (MoCA), which relies on intact visuospatial and language function for completion.

While the MoCA has acceptable test properties for use as an initial screening test in a stroke population, consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the MoCA cognitive screening test should be fully trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive MoCA test result and findings should be shared with the stroke care team.

8.8 Accuracy of Folstein's Mini-Mental State Examination for contemporaneous diagnosis of dementia

Weak recommendation

We suggest that in acute and post-acute stroke settings, screening of cognition using Folstein’s Mini-Mental State Examination (MMSE) be considered. MMSE should not be used as a substitute for comprehensive clinical assessment.

At the conventional threshold for test positivity, MMSE screening will exclude most stroke survivors with no important cognitive issues, but at the cost of substantial false negatives.

Quality of evidence: Low ⊕⊕

Consensus recommendation

There are inherent limitations to the Mini Mental State Examination (MMSE), which relies on intact visuospatial and language function for completion.

While the MMSE has acceptable test properties for use as an initial screening test in a stroke population, consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the MMSE cognitive screening test should be fully trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive MMSE test and findings should be shared with the stroke care team.

8.9 Accuracy of Addenbrooke’s Cognitive Examination (ACE) for contemporaneous diagnosis of dementia
Weak recommendation

We suggest that in acute and post-acute stroke settings, screening of cognition with one of the versions of the Addenbrookes Cognitive Examination (ACE) can be considered. ACE should not be used as a substitute for comprehensive clinical assessment.

Test properties are sensitive to the threshold used to define test positivity, but there were insufficient data to make recommendations around the optimal cut-off for use in stroke.

Quality of evidence: Very Low ⊕

Consensus recommendation

There are inherent limitations to the various versions of the Addenbrookes Cognitive Examination (ACE), which all rely on intact visuospatial and language function for completion.

Acceptable test properties for the ACE have not been established for use as an initial screening test in a stroke population and consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the ACE cognitive screening test should be trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive ACE test result and findings should be shared with the stroke care team.

8.10 Accuracy of the Oxford Cognitive Screen (OCS) for contemporaneous diagnosis of dementia

There is insufficient published evidence to assess the accuracy of the Oxford Cognitive Screen (OCS) for contemporaneous diagnosis of dementia in the stroke setting.

Future research should assess the diagnostic accuracy and utility of the OCS for post-stroke cognitive syndromes.

Quality of evidence: Very Low ⊕

Consensus recommendation

The Oxford Cognitive Screen (OCS) offers advantages over other screening tools in terms of ease of completion and feasibility for stroke survivors with physical, language or visuospatial impairments.

Test accuracy studies of the OCS as a screen for post stroke dementia are required.

Those utilising the OCS should be trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive OCS and findings should be shared with the stroke care team.

8.11 Accuracy of remote assessment for contemporaneous diagnosis of dementia
We suggest that in post-acute stroke settings, telephone-based screening of cognition can be considered. Telephone-based cognitive screening is not a substitute for comprehensive clinical assessment. At conventional thresholds for test positivity, telephone-based screening will detect most people with important cognitive issues but at the cost of substantial false positives. Test properties are sensitive to the threshold used to define test positivity, but there were insufficient data to make recommendations around the optimal cut-off for use in stroke.

Quality of evidence: Very Low ⊕

There are inherent limitations to telephone based cognitive screening, but telephone screening can be useful in situations where in-person assessment is not practical. Video call based cognitive screening shows promise in stroke, but further studies and best practice guidance around application and interpretation of results is needed. Consideration should be given to the development and validation of specific telephone or video call cognitive screening tools or protocols. Those utilising remote cognitive screening tests should be trained in their administration. Further comprehensive cognitive assessment is recommended in the event of a positive screening test result and findings should be shared with the stroke care team.

8.12 Cholinesterase inhibitors for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden

In people living with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of cholinesterase inhibitors for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden.

Quality of evidence: Very Low ⊕

In people living with post stroke dementia, any beneficial effect of cholinesterase inhibitors is likely to be modest, and perhaps not clinically relevant, the risk of adverse events should also be considered. In a predominantly vascular cognitive impairment the effect of these drugs is minimal, but many older adults with stroke have other neurodegenerative diseases that may benefit from cholinesterase inhibitors. We recognise that excluding co-existant Alzheimer’s disease or other neurodegenerative processes can be difficult in older adults with stroke and if the diagnosis is of probable mixed pathology then cholinesterase inhibitors may be considered. Stroke should not be a barrier to considering treatment with cholinesterase inhibitors if suspected concomitant Alzheimer’s disease or Lewy Body dementia.

8.13 Memantine for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden
In people living with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of memantine for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden.

Quality of evidence: Very Low ⊕

Consensus recommendation

In people living with post stroke dementia, any beneficial effect of memantine is likely to be modest, and perhaps not clinically relevant, the risk of adverse events should also be considered.

In a predominantly vascular cognitive impairment, the effect of memantine is minimal, but many older adults with stroke have other neurodegenerative diseases that may benefit from this drug. We recognise that excluding co-existant Alzheimer’s disease can be difficult in older adults with stroke and if the diagnosis is of probable mixed pathology then memantine may be considered.

Stroke should not be a barrier to considering treatment with memantine if suspected concomitant moderate to severe Alzheimer’s disease.

8.14 Actovegin or cerebrolysin for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden

Actovegin

In patients with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of actovegin.

Quality of evidence: Very Low ⊕

Cerebrolysin

In patients with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of cerebrolysin.

Quality of evidence: Very Low ⊕

Consensus recommendation

The available evidence suggests that any cognitive benefits of actovegin and cerebrolysin are likely to be modest and there is risk of serious adverse events with treatment. Considering the balance of risks and harms, we suggest against using these agents for post stroke cognitive impairment.

Replication of the single available trial for Actovegin is needed.

Any further trials of actovegin and cerebrolysin should be adequately powered, have longer term follow-up and consider patient reported outcomes and health economic measures.

8.15 Cognitive rehabilitation for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden

Due to a lack of methodologically robust trials, for most cognitive rehabilitation interventions, there is continued uncertainty on the benefits and limitations associated with these interventions for stroke survivors.

Quality of evidence: Very low ⊕
Consensus recommendation

Although many of the available studies did not meet our inclusion criteria for this PICO, there is emerging evidence that cognitive rehabilitation, particularly compensatory strategies in the context of individually relevant functional tasks, may be beneficial for people with post-stroke cognitive impairments.

Methodologically robust trials to support definitive recommendations for clinical practice are needed.

8.16 Multi-item prognostic tools for the prediction of future cognitive decline or dementia

There is continued uncertainty over the advantages and disadvantages of using multi-item prognostic tools to predict cognitive outcomes following stroke.

Quality of evidence: Very Low

Consensus recommendation

The quality of supporting evidence for tools to predict cognitive syndromes (incident delirium or dementia) is not sufficient to recommend their use in routine stroke care.

Further studies of prognostic tools for post-stroke cognitive syndromes should follow best practice guidance in prognosis methods and pay particular attention to ensuring appropriate sample size, handling missing data and external validation in independent populations.

Trials that assess the utility of using a prediction tool in clinical practice are also warranted.

8.17 Structural features on acute brain CT imaging for the prediction of future cognitive decline or dementia

In patients with acute stroke there is continued uncertainty regarding the value of acute CT-brain imaging findings for predicting cognitive outcomes more than one year after stroke.

Quality of evidence: Very Low

Consensus recommendation

As CT is the most widely available and commonly used imaging modality in acute stroke, a better understanding of the prognostic value of the imaging findings for future cognitive prognosis would be useful.

Further studies of the predictive value of CT-based imaging variables should use standardized measurements and validated tools.

Consideration needs to be given to the population included, with preferably unselected samples and low rates of attrition from cognitive follow-up.

Results of these studies need appropriate adjustments to distinguish the added prognostic value of CT imaging features over standard clinical factors such as age, sex and stroke severity.

8.18 Structural features on acute brain MR imaging for the prediction of future cognitive decline or dementia
Weak recommendation

White matter hyperintensities

We suggest that in patients with acute stroke, the presence of substantial white matter hyperintensities of presumed vascular origin on acute MRI brain may help predict cognitive outcomes more than one year after stroke.

Quality of evidence: Moderate 🗓️ 🗓️ 🗓️

Acute MRI brain imaging findings

In patients with acute stroke there is continued uncertainty regarding the value of acute MRI brain imaging findings, other than white matter hyperintensities, to predict cognitive outcomes more than one year after stroke.

Quality of evidence: Very Low 🗓️

Consensus recommendation

At present, the evidence for prognostic utility in predicting future cognitive decline after stroke is most convincing for white matter lesions.

However, the added predictive value of imaging findings over and above routinely acquired clinical factors remains uncertain.

Further studies of the predictive value of MRI-based imaging variables should use standardized measurements and validated tools.

Consideration needs to be given to the population included, with preferably unselected samples and low rates of attrition from cognitive follow-up.

Results of these studies need appropriate adjustments to distinguish the added prognostic value of MRI imaging features over standard clinical factors such as age, sex and stroke severity.

3. Abstract

Introduction: The optimal management of post stroke cognitive impairment remains controversial. These joint European Stroke Organisation (ESO) and European Academy of Neurology (EAN) guidelines provide evidence-based recommendations to assist clinicians in decision making around prevention, diagnosis, treatment, and prognosis.

Methods: These guidelines were developed according to ESO standard operating procedure and the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) methodology. The working group identified relevant clinical questions, performed systematic reviews and, where possible, meta-analyses of the literature, assessed the quality of the available evidence, and made specific recommendations. Expert consensus statements were provided where insufficient evidence was available to provide recommendations based on the GRADE approach.

Results: There was limited randomised controlled trial evidence regarding single or multicomponent interventions to prevent post stroke cognitive decline. Interventions to improve lifestyle and treat vascular risk factors may have many health benefits but a beneficial effect on cognition is not proven. We found no evidence around routine cognitive screening following stroke but recognise the importance of targeted cognitive assessment. We described the accuracy of various cognitive screening tests but found no clearly superior approach to testing. There was insufficient evidence to make a recommendation for use of cholinesterase inhibitors, memantine nootropics or cognitive rehabilitation. There was limited evidence on the use of prediction tools for post stroke cognitive syndromes (cognitive impairment, dementia and delirium). The association between post stroke cognitive impairment and most acute structural brain imaging features was unclear, although the presence of substantial white matter hyperintensities of presumed vascular origin on acute MRI brain may help predict cognitive outcomes.

Conclusions: These guidelines have highlighted fundamental areas where robust evidence is lacking. Further, definitive randomised controlled trials are needed and we suggest priority areas for future research.
4. Summary table of recommendations

**PICO 1:** In people with a history of stroke, do monitored lifestyle-based interventions (exercise, dietary change, alcohol moderation, weight loss, smoking cessation), alone or in combination, compared to care as usual, prevent: future cognitive decline or dementia?

**Recommendation**

We cannot recommend monitored lifestyle interventions solely for the prevention of post-stroke cognitive decline or dementia.

Quality of evidence: **Very Low ⊕⊕**

Strength of recommendation: **No recommendation**

*(This recommendation only relates to the cognitive effects of lifestyle interventions)*

**Expert Consensus Statement**

Lifestyle interventions, alone or in combination, should not be used solely for the prevention of post-stroke cognitive decline or dementia. Other benefits, such as a better physical or mental health or the prevention of future cardiovascular disease may warrant recommendations on lifestyle after stroke, but these were not the focus of this guideline.

There is a need for further, adequately powered trials that assess the effect of monitored lifestyle interventions on cognitive outcomes following stroke.

**PICO 2:** In people with a history of stroke, does monitored intensive management of vascular risk factors, compared to usual care, prevent: future cognitive decline or dementia?

**Recommendation**

**Blood pressure treatment.**

We cannot recommend intensive treatment of blood pressure compared to usual care solely for the prevention of post-stroke cognitive decline and dementia.

Quality of evidence: **Very Low ⊕⊕**

Strength of recommendation: **No recommendation**

*(This recommendation only relates to cognitive effects of blood pressure treatment)*

**Antithrombotic therapy.**

We suggest against using dual antiplatelet therapy compared to single antiplatelet therapy for the prevention of cognitive decline in lacunar stroke.

Quality of evidence: **Very Low ⊕⊕**

Strength of recommendation: **Weak against intervention ↓?**

*(This recommendation relates to cognitive effects of dual antiplatelet and is applicable to lacunar stroke only)*
Statin treatment.

We cannot recommend intensive statin treatment compared to usual care solely for the prevention of post-stroke cognitive decline or dementia.

Quality of evidence: Very Low ⬤
Strength of recommendation: No recommendation
(This recommendation only relates to cognitive effects of statin treatment)

Expert Consensus Statement

Given the beneficial effects of vascular risk management on prevention of recurrent stroke and cardiovascular disease, comprehensive risk factor management including blood pressure reduction, antithrombotic and statin is warranted following stroke, even though the cognitive benefits are unclear.

Targets for stroke risk factor management are constantly evolving and approaches that were historically considered 'intensive' are now common practice and recommended in guidelines.

Future trials of secondary prevention in stroke should include cognitive outcome measures.

PICO 3: In people with a history of stroke, do monitored multicomponent interventions (lifestyle and pharmacological), compared to usual care, prevent: future cognitive decline or dementia?

We cannot recommend multicomponent interventions (including medications and lifestyle interventions) solely for the prevention of post-stroke cognitive decline or dementia.

Quality of evidence: Very Low ⬤
Strength of recommendation: no recommendation
(This recommendation only relates to the cognitive effects of multicomponent interventions)

Expert Consensus Statement

All but one of the writing group agreed that:

Monitored multicomponent interventions, cannot be recommended for the prevention of cognitive decline or dementia following stroke alone, but there are other potential health benefits associated with these lifestyle interventions, such as the prevention of future cardiovascular disease or recurrent stroke.
**PICO 4:** In people with a history of stroke, does cognitive training, compared to usual care prevent future cognitive decline or future dementia?

**Recommendation**

There is continued uncertainty over the benefits and limitations of cognitive training for the prevention of cognitive decline and dementia in people living with stroke.

**Quality of evidence:** Very Low ⚫

**Strength of recommendation:** No recommendation

**Expert Consensus Statement**

All but one of the writing group agreed that:

Cognitive training could be considered following stroke as part of a broader rehabilitation package. However, based on the current available literature, there is no evidence that cognitive training, as a single intervention, has a clinically meaningful or sustained benefit for prevention of cognitive decline or dementia following stroke.

---

**PICO 5:** In people with a history of post-stroke dementia does, stopping pharmacological management of vascular risk factors (de-prescribing), compared to continuing these medications prevent future cognitive decline or improve health related quality of life

**Recommendation**

There is continued uncertainty over the benefits and risks of continuing treatment with antihypertensive or statin medications compared to withdrawal of these medications for cognitive or quality of life outcomes in people living with post-stroke dementia.

**Quality of evidence:** Very Low ⚫

**Strength of recommendation:** No recommendation

**Expert Consensus Statement**

Given the beneficial effect on cardiovascular disease/stroke prevention and no clear signal of cognitive harm, pharmacological vascular risk factor management should be continued in patients with mild to moderate post-stroke dementia.

In people living with more advanced dementia and short life expectancy, where the potential harms and burden of treatment may be greater than any vascular protection, the benefits of continuing stroke secondary prevention medications are unclear.

Pragmatic trials of deprescribing medications are needed to guide treatment decisions in people living with advanced post-stroke dementia.

---

**PICO 6:** In patients with stroke, does routine use of cognitive assessment, compared to no routine screening, improve stroke care.

**Recommendation**

Due to a lack of relevant trials in patients with stroke, there is continued uncertainty over the benefits and risks of routine cognitive screening to improve stroke care.
Quality of evidence: Very Low

Strength of recommendation: no recommendation

*(this recommendation applies only to routine screening of all patients presenting with stroke, and does not apply to clinician directed assessment)*

**Expert Consensus Statement**

Cognitive screening should be considered as part of the comprehensive assessment of stroke survivors.

However, there are insufficient data to make recommendations around the timing, the content or the potential benefits of cognitive screening to the patient, their care-givers, and to healthcare systems.

Further studies describing the effects of routine cognitive screening following stroke are required. These studies should include acute stroke settings, should record feasibility and acceptability, consider effects on care pathways, and describe care-giver outcomes and health economics.

**PICO 7:** In patients with stroke (acute or post-acute), what is the accuracy of Montreal Cognitive Assessment for contemporaneous diagnosis of post-stroke cognitive impairment or dementia?

**Recommendation**

We suggest that in post-acute stroke settings, screening of cognition using the Montreal Cognitive Assessment (MoCA) is considered.

MoCA should not be used as a substitute for comprehensive clinical assessment.

At the conventional threshold for test positivity, MoCA screening will detect most stroke survivors with important cognitive issues but at the cost of substantial false positives.

We suggest that a revised (lower) threshold be considered for stroke populations.

Quality of evidence: Low

Strength of recommendation: Weak for intervention

**Expert Consensus Statement**

There are inherent limitations to the Montreal Cognitive Assessment (MoCA), which relies on intact visuospatial and language function for completion.

While the MoCA has acceptable test properties for use as an initial screening test in a stroke population, consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the MoCA cognitive screening test should be fully trained in its administration.
Further comprehensive cognitive assessment is recommended in the event of a positive MoCA test result and findings should be
shared with the stroke care team.

**PICO 8:** In patients with stroke (acute or post-acute), what is the accuracy of Folstein's **Mini-Mental State Examination** for
contemporaneous diagnosis of dementia?

**Recommendation**

We suggest that in acute and post-acute stroke settings, screening of cognition using Folstein’s Mini-Mental State Examination
(MMSE) be considered.

MMSE should not be used as a substitute for comprehensive clinical assessment.

At the conventional threshold for test positivity, MMSE screening will exclude most stroke survivors with no important cognitive
issues, but at the cost of substantial false negatives.

**Quality of evidence:** Low ⊕⊕

**Strength of recommendation:** Weak for intervention ↑?

**Expert Consensus Statement**

There are inherent limitations to the Mini Mental State Examination (MMSE), which relies on intact visuospatial and language
function for completion.

While the MMSE has acceptable test properties for use as an initial screening test in a stroke population, consideration should be
given to the development of cognition screening tools that are more acceptable and feasible for those with communication
difficulties or spatial neglect.

Those utilising the MMSE cognitive screening test should be fully trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive MMSE test and findings should be shared
with the stroke care team.

**PICO 9:** In patients with stroke (acute or post-acute), what is the accuracy of **Addenbrooke’s Cognitive Examination (ACE)** for
contemporaneous diagnosis of dementia?

**Recommendation**

We suggest that in acute and post-acute stroke settings, screening of cognition with one of the versions of the Addenbrookes
Cognitive Examination (ACE) can be considered.

ACE should not be used as a substitute for comprehensive clinical assessment.
Test properties are sensitive to the threshold used to define test positivity, but there were insufficient data to make recommendations around the optimal cut-off for use in stroke.

**Quality of evidence:** Very Low ⊕

**Strength of recommendation:** Weak for intervention ↑?

**Expert Consensus Statement**

There are inherent limitations to the various versions of the Addenbrookes Cognitive Examination (ACE), which all rely on intact visuospatial and language function for completion.

Acceptable test properties for the ACE have not been established for use as an initial screening test in a stroke population and consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the ACE cognitive screening test should be trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive ACE test result and findings should be shared with the stroke care team.

**PICO 10. In patients with stroke (acute or post-acute), what is the accuracy of the Oxford Cognitive Screen (OCS) for contemporaneous diagnosis of dementia?**

**Recommendation**

There is insufficient published evidence to assess the accuracy of the Oxford Cognitive Screen (OCS) for contemporaneous diagnosis of dementia in the stroke setting.

Future research should assess the diagnostic accuracy and utility of the OCS for post-stroke cognitive syndromes.

**Quality of evidence:** Very Low ⊕

**Strength of recommendation:** no recommendation

**Expert Consensus Statement**

The Oxford Cognitive Screen (OCS) offers advantages over other screening tools in terms of ease of completion and feasibility for stroke survivors with physical, language or visuospatial impairments.

Test accuracy studies of the OCS as a screen for post stroke dementia are required.

Those utilising the OCS should be trained in its administration.
Further comprehensive cognitive assessment is recommended in the event of a positive OCS and findings should be shared with the stroke care team.

### PICO 11.

In patients with stroke (acute or post-acute), what is the accuracy of remote assessment for contemporaneous diagnosis of dementia?

### Recommendation

We suggest that in post-acute stroke settings, telephone-based screening of cognition can be considered. Telephone-based cognitive screening is not a substitute for comprehensive clinical assessment.

At conventional thresholds for test positivity, telephone-based screening will detect most people with important cognitive issues but at the cost of substantial false positives.

Test properties are sensitive to the threshold used to define test positivity, but there were insufficient data to make recommendations around the optimal cut-off for use in stroke.

**Quality of evidence:** Very Low 🌟

**Strength of recommendation:** Weak for intervention ↑?

### Expert Consensus Statement

There are inherent limitations to telephone based cognitive screening, but that telephone screening can be useful in situations where in-person assessment is not practical.

Video call based cognitive screening shows promise in stroke, but further studies and best practice guidance around application and interpretation of results is needed.

Consideration should be given to the development and validation of specific telephone or video call cognitive screening tools or protocols.

Those utilising remote cognitive screening tests should be trained in their administration.

Further comprehensive cognitive assessment is recommended in the event of a positive screening test result and findings should be shared with the stroke care team.

### PICO 12:

In people with post-stroke cognitive impairments, do cholinesterase inhibitors, compared to placebo, delay cognitive decline or progression to dementia; improve behavioural and psychological symptoms, decrease caregiver burden and/or cause adverse effects?

### Recommendation

In people living with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of cholinesterase inhibitors for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden.
Quality of evidence: Very Low ⬤ ⬤
Strength of recommendation: No recommendation

Expert Consensus Statement

In people living with post stroke dementia, any beneficial effect of cholinesterase inhibitors is likely to be modest, and perhaps not clinically relevant, the risk of adverse events should also be considered.

In a predominantly vascular cognitive impairment the effect of these drugs is minimal, but many older adults with stroke have other neurodegenerative diseases that may benefit from cholinesterase inhibitors.

We recognise that excluding co-existant Alzheimer’s disease or other neurodegenerative processes can be difficult in older adults with stroke and if the diagnosis is of probable mixed pathology then cholinesterase inhibitors may be considered.

Stroke should not be a barrier to considering treatment with cholinesterase inhibitors if suspected concomitant Alzheimer’s disease and Lewy Body dementia.

PICO 13: In people with post-stroke cognitive impairments, does memantine compared to placebo, delay cognitive decline or progression to dementia, improve behavioural and psychological symptoms, decrease caregiver burden and/or cause adverse effects?

Recommendation

In people living with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of memantine for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden.

Quality of evidence: Very Low ⬤ ⬤
Strength of recommendation: no recommendation

Expert Consensus Statement

In people living with post stroke dementia, any beneficial effect of memantine is likely to be modest, and perhaps not clinically relevant, the risk of adverse events should also be considered.

In a predominantly vascular cognitive impairment, the effect of memantine is minimal, but many older adults with stroke have other neurodegenerative diseases that may benefit from this drug.

We recognise that excluding co-existant Alzheimer’s disease can be difficult in older adults with stroke and if the diagnosis is of probable mixed pathology then memantine may be considered.

Stroke should not be a barrier to considering treatment with memantine if suspected concomitant moderate to severe Alzheimer’s disease.

PICO 14: In people with post-stroke cognitive impairments, do the nootropics actovegin or cerebrolysin, compared to placebo improve cognitive decline, improve behavioural and psychological symptoms, reduce caregiver burden and/or increase adverse events.
Recommendation

In patients with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of actovegin.

Quality of evidence: Very Low

Strength of recommendation: No recommendation

In patients with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of cerebrolysin.

Quality of evidence: Very Low

Strength of recommendation: No recommendation

Expert Consensus Statement

The available evidence suggests that any cognitive benefits of actovegin and cerebrolysin are likely to be modest and there is risk of serious adverse events with treatment. Considering the balance of risks and harms, we suggest against using these agents for post stroke cognitive impairment.

Replication of the single available trial for Actovegin is needed.

Any further trials of actovegin and cerebrolysin should be adequately powered, have longer term follow-up and consider patient reported outcomes and health economic measures.

PICO 15: In people with post-stroke cognitive impairments, does cognitive rehabilitation (cognitive skill training or compensation strategies) compared to no rehabilitation, delay cognitive decline or progression to dementia, improve behavioural and psychological symptoms, improve performance in activities of daily living or decrease caregiver burden?

Recommendation

Due to a lack of methodologically robust trials, for most cognitive rehabilitation interventions, there is continued uncertainty on the benefits and limitations associated with these interventions for stroke survivors.

Quality of evidence: Very low

Strength of recommendation: no recommendation

Expert Consensus Statement

Although many of the available studies did not meet our inclusion criteria for this PICO, there is emerging evidence that cognitive rehabilitation, particularly compensatory strategies in the context of individually relevant functional tasks, may be beneficial for people with post-stroke cognitive impairments.
Methodologically robust trials to support definitive recommendations for clinical practice are needed.

PICO 16. In people with a history of stroke, do multi-item prognostic tools performed soon after stroke, predict future cognitive decline or dementia.

**Recommendation**

There is continued uncertainty over the advantages and disadvantages of using multi-item prognostic tools to predict cognitive outcomes following stroke.

Quality of evidence: Very Low

Strength of recommendation: No recommendation

**Expert Consensus Statement**

The quality of supporting evidence for tools to predict cognitive syndromes (incident delirium or dementia) is not sufficient to recommend their use in routine stroke care.

Further studies of prognostic tools for post-stroke cognitive syndromes should follow best practice guidance in prognosis methods and pay particular attention to ensuring appropriate sample size, handling missing data and external validation in independent populations.

Trials that assess the utility of using a prediction tool in clinical practice are also warranted.

PICO 17: In people with a history of stroke, do structural features on acute brain CT imaging, predict (at least one year from index stroke event) future cognitive decline or dementia.

**Recommendation**

In patients with acute stroke there is continued uncertainty regarding the value of acute CT-brain imaging findings for predicting cognitive outcomes more than one year after stroke.

Quality of evidence: Very low

Strength of recommendation: no recommendation

**Expert Consensus Statement**

As CT is the most widely available and commonly used imaging modality in acute stroke, a better understanding of the prognostic value of the imaging findings for future cognitive prognosis would be useful.

Further studies of the predictive value of CT-based imaging variables should use standardized measurements and validated tools.

Consideration needs to be given to the population included, with preferably unselected samples and low rates of attrition from cognitive follow-up.
Results of these studies need appropriate adjustments to distinguish the added prognostic value of CT imaging features over standard clinical factors such as age, sex and stroke severity.

| PICO 18 | In people with a history of stroke, **do structural features on acute brain MR imaging**, predict (at least one year from index stroke event) future cognitive decline or dementia. |

**Recommendation**

We suggest that in patients with acute stroke, the presence of substantial white matter hyperintensities of presumed vascular origin on acute MRI brain may help predict cognitive outcomes more than one year after stroke.

Quality of evidence: **Moderate** ⬤ ⬤ ⬤

Strength of recommendation: **Weak for intervention** ↑?

In patients with acute stroke there is continued uncertainty regarding the value of acute MRI brain imaging findings, other than white matter hyperintensities, to predict cognitive outcomes more than one year after stroke.

Quality of evidence: **Very Low** ⬤

Strength of recommendation: no recommendation

**Expert Consensus Statement**

At present, the evidence for prognostic utility in predicting future cognitive decline after stroke is most convincing for white matter lesions.

However, the added predictive value of imaging findings over and above routinely acquired clinical factors remains uncertain.

Further studies of the predictive value of MRI-based imaging variables should use standardized measurements and validated tools.

Consideration needs to be given to the population included, with preferably unselected samples and low rates of attrition from cognitive follow-up.

Results of these studies need appropriate adjustments to distinguish the added prognostic value of MRI imaging features over standard clinical factors such as age, sex and stroke severity.
5. Plain Language Summary

Problems with memory and thinking are common following stroke. Thankfully, for many stroke survivors these problems improve over time, but for some people the problems persist and can have a major effect on independence and quality of life. When memory and thinking problems are severe, we may use the term post-stroke dementia.

There are lots of potential interventions for the memory and thinking problems that can follow stroke. Across Europe healthcare professionals use differing approaches to treatment with little consensus on the optimal strategy. In this situation, a guideline that makes recommendations on best practice can be useful.

In this guideline we collected relevant scientific studies that looked at post-stroke memory and thinking. We divided the guideline into four sections, prevention, diagnosis, treatment, and prediction (prognosis). Each section was written by a team of experts who reviewed all the available research. Where possible we combined the results of studies and compared different treatments. If the published studies couldn't give a definitive answer, we used the knowledge and experience of our expert writing group of healthcare professionals and researchers to offer practical guidance.

For the prevention section, we found very few studies that described the effects of medications or lifestyle on memory and thinking following a stroke. Actions such as taking medications for high blood pressure and getting more exercise seem to have lots of health benefits and are generally recommended. However, we don't know if these actions also prevent dementia and other thinking problems following a stroke.

There is no doubt that accurate diagnosis of dementia is important where there is a concern regarding memory and thinking. Some stroke services screen every new stroke patient for dementia. We found no studies that have tested this approach. We did find several different pencil and paper tests that can be used for the assessment of memory and thinking problems. Many of these tests have been used in stroke survivors. Looking at the accuracy of the tests, there was no clearly superior option. In choosing an assessment for a stroke survivor, it is important to consider the whole person – can they hold a pen, do they have the energy to complete a long test. With Covid-19 restrictions, many services have started using telephone or video call assessments. Despite the increasing use of these technologies, we found very few studies on the topic.

We looked at treatment of post-stroke dementia using those medications that are often prescribed to people with Alzheimer’s dementia – cholinesterase inhibitors and memantine. There were very few studies that assessed these medications in stroke survivors. We concluded that having a stroke shouldn't be a barrier to prescribing these medications to a person with dementia who otherwise would be suitable for treatment. However, we couldn't make a recommendation around using these medications for all people with post-stroke dementia. In some parts of Europe, animal derived compounds (nootropics) have been used to help brain recovery following stroke. Again, there were few studies with a specific focus on memory and thinking. Where studies were available, we had concerns around the potential burden, cost and safety of these treatments. A large part of the treatment of memory and thinking issues involves rehabilitation. Although we found many studies looking at methods of rehabilitation, most had too few participants or did not look at longer term effects. So, we are still uncertain as to the best methods of rehabilitation for memory and thinking problems following stroke.

If we could predict who would develop important and persisting memory and thinking problems following a stroke, we could target our treatments accordingly. There are lots of individual factors that are associated with risk of dementia following a stroke. We looked at whether combining these factors into a prediction score could identify those people who would develop problems. We found various examples of dementia prediction tools, but no tool was good enough to be used in clinical practice. Finally, we looked at whether brain scans, performed as part of usual stroke care, could help identify people who will develop memory and thinking issues. Results of studies were mixed and often conflicting. One feature seen on MRI brain scans, abnormal signals in the deep structures of the brain, did consistently seem to be associated with future risk of dementia and related issues. However, it is not clear if using this MRI feature improves prediction over and above standard clinical judgement.

Although we reviewed a lot of scientific studies, for many of the questions in our guideline we concluded that there simply isn’t enough information to give a definitive answer. This is frustrating for researchers and clinicians, but it also allows us to select priority areas to target future research studies. We would hope that updated versions of this guideline can properly address these important aspects of stroke care.
6. Introduction

Cognitive impairment is a common and potentially disabling effect of stroke.[1] Post stroke cognitive impairment is a collective term for differing pathological processes, but regardless of the underlying aetiology, stroke survivors and their caregivers consistently rate problems of memory and thinking as their greatest concern.[2] Despite the importance of post stroke cognitive problems, this is an area of stroke care where there are substantial rates of underdiagnosis in clinical practice, and a disproportionate lack of research activity. As a result, there is substantial variation in management of post stroke cognitive issues across Europe. It is noticeable that post stroke cognitive impairment is mentioned in only a small number of the many national and international guidelines available for stroke care. The apparent disconnect between clinical relevance and available evidence is thankfully changing, large cohorts and other studies are underway which should help us better understand and manage post stroke cognitive impairment.[3] In the meantime, clinicians may benefit from a synthesis of the available research that allows evidence based, or expert informed, guidance on post stroke cognitive impairment.

In this context the European Stroke Organisation (ESO) commissioned a guideline, in agreement with the Stroke Scientific Panel of the European Academy of Neurology (EAN), with a focus on post stroke cognitive impairment. The intention with this guideline was to provide a useful resource for health professionals and researchers from multiple disciplines, as well as policy makers. Recognising that the potential scope of this guideline was broad, we chose to focus on four specific areas of clinical importance: prevention, diagnosis, management, and prognosis.

The guideline followed best practice and adhered to the standard operating procedure of the ESO Guideline Group.[4] The methods that informed the formulation of our recommendations and consensus statements are described later in the text. However, there are certain aspects of our approach that are worthy of mention early in the guideline and will be discussed here.

In planning the work, we were keen that we represent all the clinical disciplines involved in managing people living with stroke and subsequent post stroke cognitive issues. Thus, we stipulated that our core guideline writing group would comprise expertise in geriatric medicine, psychology, psychiatry, neuropsychology, neurology, occupational therapy in addition to a representative of a stroke society.

Arguably a barrier to progress in the broad field of vascular cognitive impairment is the lack of consensus definitions for the syndromes of interest.[5] In this guideline we took an inclusive approach, defining the concept of post stroke cognitive impairment, as all problems in cognitive function that occur following a stroke, irrespective of the aetiology. We make a deliberate distinction between the broad construct of cognitive impairment and the more defined concept of dementia (or major neurocognitive disorder) and we consider the two constructs separately in the guideline. For many of our questions we consider the concept of cognitive decline i.e. change in cognitive function over time.

It would be almost impossible to cover every important clinical question that is relevant to the field of post stroke cognitive impairment.[6] We did not restrict our remit to those areas where we knew we would find high quality trials. Rather, we turned our attention to those aspects of stroke care where we felt the need for clinical guidance was most pressing. To achieve this, we used relatively novel approaches to evidence synthesis. We were aware that for some topics definitive answers could not be achieved with this methodology. We planned that where an evidence-based recommendation was not possible, we would provide an expert opinion taking in consideration all the available information and drawing on the experience and knowledge of our multidisciplinary writing group.

The stroke dementia research space has been criticised for having too many small studies with inherent methodological limitations.[6] To ensure our recommendations did not suffer from the same biases, for many of our PICO questions, we pre-specified strict inclusion criteria around study method (randomised controlled trials – RCTs), population size, duration of follow-up and study design. Applying these criteria necessarily means that certain well-known papers would not be included in the evidence that informed our recommendations. We felt that post stroke cognitive impairment was too important to allow the inclusion of potentially misleading studies. Anticipating that some areas may have few included studies, as a final part of the guideline writing process, we used the available evidence to select key research questions that should be a priority for future studies.
7. Methods

Composition of the writing group

These guidelines were jointly initiated by the ESO and EAN. A Module Working Group (MWG) was established, consisting of 15 experts (TQ, HSM, co-Chairs). The MWG was joined by four fellows (MH, HH, BAD, EB) who assisted with abstract and full text screening, data extraction and drafting the text. Fellows were all either trainee neurologists or post-doctoral fellows interested in stroke or neuro-epidemiology. The composition of the MWG was designed to include those disciplines involved in the care of people living with post stroke cognitive issues and comprised multidisciplinary expertise. Attention was given to achieving diversity in terms of sex and geography. The group included the Chief Executive Officer of the Danish Stroke Association to facilitate stroke survivor views. The composition of this group was approved by the ESO Guidelines Board and the ESO Executive Committee, based on a review of the intellectual and financial disclosures of the proposed members.

Selection of Population, Intervention, Comparator, and Outcome

The guidelines were developed using Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) methodology[7] and the ESO Standard Operating Procedure.[4]

The MWG developed a list of topics, and corresponding outcomes of clinical interest. The outcomes were rated as critical, important or of limited importance according to GRADE criteria. The MWG voted in a closed ballot to identify which questions were highest priority.

After initial scoping meetings, four sub-groups were formed to develop recommendations in thematic areas of prevention, diagnosis, treatment and prognosis. Each subgroup had a chair and at least two other members (see contribution section for details of each subgroup).

These subgroups formulated three to five main PICO (Population, Intervention, Comparator, Outcome) questions. The outcomes chosen for each PICO favoured those rated as ‘critical’ by the MWG. These were subsequently approved by the ESO Guidelines board and the ESO Executive Committee.

For each PICO question, search terms were identified, tested, refined and agreed by each writing subgroup. Search terms were developed in partnership with the Cochrane Dementia Group. Where a validated search strategy was available this was used or adapted. Where there was a recent relevant systematic review on the question of interest, the corresponding search strategy and results were used and updated as necessary. Each search strategy is described in the Supplementary materials.

Identification and selection relevant studies

At least two members of each writing subgroup independently screened the titles and abstracts of publications and assessed the full text of potentially relevant studies. We focused on randomized controlled trials but considered other types of study such as health registry data analyses and large observational studies since we anticipated a lack of high quality RCTs. We noted potentially relevant ongoing studies for future reference. All disagreements were resolved by discussion between the two authors or by a third MWG author. We searched reference lists of review articles, the authors own reference libraries, and previous guidelines for additional relevant material.

Recognizing the potential limitations in the post stroke cognition field, we made a series of a-priori decisions around inclusion, considering study methodology, sample size and duration of follow-up. These are detailed in the corresponding PICO sections.

For each question, the writing subgroup, assisted by one or more fellows, evaluated the available evidence. The risk of selection, performance, detection, attrition and reporting biases in each randomised trial was assessed. For randomised controlled trials, the assessment used the standard Cochrane tool.[8] This guideline was not restricted to interventional RCTs and we adapted our assessment of risk of bias and quality of evidence to suit the component data.9 Where the assessment did not use the standard approach outlined in the ESO guideline Standard Operating Procedure, any modification, and the relevant tools employed, are described in the relevant PICO section. In the evidence synthesis, we did not use an overall quality ‘score’ as such an approach is now discouraged.[9] The classification of low or high risk of bias was performed by the assessors at individual study level.

For each PICO question, the quality of evidence was rated using the GRADEpro Guideline Development Tool (McMaster University, 2015; developed by Evidence Prime, Inc.) using guidelines for non-pooled data as necessary.[7] Final quality ratings were categorised as high, moderate, low or very low. GRADE assessment was performed within writing subgroups and then shared with the complete MWG for discussion and consensus. Text was discussed in open forum through monthly team calls, members of the complete MWG then voted on the text using a Delphi approach. Complete consensus was required for the Recommendation statements and text was revised until consensus was reached. For Expert Consensus Statements, complete consensus was not mandated, but where there was disagreement in the group this was described as part of the Statement.

The writing subgroups analysed the available primary and any additional data, prepared tables and figures and drafted three sections of text: ‘analysis of current evidence’ which focused on relevant primary studies and/or systematic reviews; ‘additional information’ to
summarise indirect evidence and provide context and 'expert consensus statement' which allowed for practical guidance where the available evidence was not sufficient to support a recommendation. Here the processes of ESO and EAN have certain differences. The EAN collate indirect evidence under a heading 'good clinical practice statements', whereas ESO collate additional relevant information and expertise under a heading of 'Expert Consensus Statement'. We followed the ESO process and terminology in formulating our text.

The Expert Consensus Statements are based on voting by all expert MWG members. Importantly, these Expert Consensus Statements should not be regarded as evidence-based recommendations, since they only reflect the opinion of the MWG. Where there was not complete consensus across all members of the MWG this is described as part of the Consensus Statement.

The Guidelines document was reviewed several times by all MWG members. Modifications to the wording of Recommendations and Expert Consensus used a Delphi approach. We required consensus for the Recommendations text. The final draft was reviewed by the Chairs of the ESO Guideline Committee and the EAN Guideline Production Group. The document was subsequently reviewed and approved by two external reviewers, members of the ESO executive committee and the Editor and peer reviewers of the European Stroke Journal.
8. Results

8.1 Monitored lifestyle-based interventions for the prevention of poststroke cognitive decline or dementia

We cannot recommend monitored lifestyle interventions solely for the prevention of post-stroke cognitive decline or dementia.

**Quality of evidence: Very Low ⊗

(This recommendation only relates to the cognitive effects of lifestyle interventions)**

**Rationale**

**PICO question:** In people with a history of stroke, do monitored lifestyle-based interventions (exercise, dietary change, alcohol moderation, weight loss, smoking cessation), alone or in combination, compared to care as usual, prevent: future cognitive decline or dementia?

**Analysis of current evidence**

The intervention of interest was non-pharmacological lifestyle interventions that are prescribed and monitored. We pre-specified that we would only include randomised controlled trials (RCTs) as observational data in the field are prone to many biases. We also pre-specified that trials would require a minimum of six months follow-up and 50 participants per arm, because we felt as a writing group that smaller, short term follow-up, studies should be considered proof of concept and are more prone to publication bias.

The literature search identified five relevant RCTs comparing monitored lifestyle-based interventions with care as usual for the prevention of future cognitive decline and dementia.

**Multidomain interventions.** Three studies examined the effects of an intervention on multiple lifestyle domain simultaneously (Austrian Polyintervention Study to Prevent Cognitive Decline after Ischemic Stroke [ASPIS][10]; blood pressure, lipid and glycaemic control, healthy diet, physical activity, and cognitive training, Ihle-Hansen et al.[11]; advice on risk factor management, smoking cessation courses, physical activity, healthy diet, Cheng et al.[12]; cognitive and rehabilitation training). These trials recruited respectively 202, 195, and 168 patients (n=565 in total), with a history of stroke. All participants were directly recruited after their initial diagnosis of stroke; two studies (Ihle-Hansen et al. and Cheng et al.) only included patients with a first ever stroke. The risk of bias in each trial was considered low (Supplementary Materials). There was no blinding of patients or staff due to the nature of the interventions, but outcome assessment was blinded. One study (Ihle-Hansen et al.) reported dementia incidence and found no effect of the intervention after 12 months (OR:0.65 (95%CI:0.24-1.48); the ASPIS study had no cases of incident dementia. Assessment instruments for cognitive decline varied widely between studies. No study reported significant change in cognitive outcomes between the intervention and control groups.

**Physical activity interventions.** Two studies investigated the effect of physical activity on cognitive decline. In total, these trials recruited 500 patients with a history of stroke, 240 patients received an exercise program delivered by physiotherapists and 254 participants received care as usual. Intervention periods ranged from 12 to 18 months, follow-up from 18 to 24 months. The Life After Stroke Trial (LAST)[13] recruited patients 3 months post-stroke, the MoveIT trial[14] within 1 month. Overall, the risk of bias in these trials was low (Supplementary Materials). There was no blinding of patients or staff due to the nature of the interventions, but outcome assessment was blinded. The LAST study found no effect of a physical activity intervention on Mini Mental State Examination (MMSE) score or Trail Making Test B (TMT-B) (between-group differences: –0.1 (95%CI:–0.8 to 0.6) and 8.6 (95%CI:–16.5 to 33.6) respectively. There was a significant difference in Trail Making Test A scores (TMT-A) in favour of the intervention group (between-group difference 8.6 (95%CI:–16.5 to 33.6)). The MoveIT trial did not find an effect on global cognitive functioning after 2-years (between group difference in Montreal Cognitive Assessment (MoCA) score -0.3, p=0.66).

Findings are summarised in table 1. In making our recommendations we considered the strength of evidence for preventing cognitive decline and dementia and limited our recommendation to those outcomes only. We recognise that lifestyle interventions have many other physical and mental health benefits and would not dissuade clinicians from trying to improve lifestyle factors for other, non-cognitive reasons. We downgraded the evidence to very low-quality evidence for imprecision, as confidence intervals included both potentially beneficial and harmful effects and imprecision, as the cognitive outcome measures used were very heterogeneous and not all validated to assess cognitive decline over time.

**Additional information**
Our literature search found unpublished RCTS that could be relevant to the PICO question. We reached out to the authors of three unpublished trials that could reasonably be finished at the time of data extraction but did not get a response (Vitality (NCT01916486), AFIVASC (NCT03578614), Bai). For the MoveIT study, we could only obtain part of the results in a conference abstract; we have contacted the study authors but did not receive a response. We found reviews of exercise interventions for preventing cognitive decline that included stroke survivors[15][16], but the included studies did not meet our inclusion criteria. The reviews concluded a possible beneficial cognitive effect of increasing physical activity but recognised methodological limitations in the studies.

**Vitamin suppletion.** Two studies (VITATOPS, VISP)[17][18] were not included as we did not regard vitamin suppletion as a monitored lifestyle intervention. Both studies investigated the effect of B-vitamin suppletion on cognitive decline and did not find an effect of this daily suppletion on cognitive decline as measured by the MMSE.

Though we found no consistent evidence that lifestyle interventions are beneficial for the prevention of post-stroke cognitive decline or dementia, there are other reasons why lifestyle changes after stroke may still be warranted, such as secondary stroke prevention, future cardiovascular disease prevention and better physical health in general.[19]

### Consensus recommendation

Lifestyle interventions, alone or in combination, should not be used solely for the prevention of post-stroke cognitive decline or dementia. Other benefits, such as a better physical or mental health or the prevention of future cardiovascular disease may warrant recommendations on lifestyle after stroke, but these were not the focus of this guideline.

There is a need for further, adequately powered trials that assess the effect of monitored lifestyle interventions on cognitive decline following stroke.

8.2 Monitored intensive management of vascular risk factors for the prevention of poststroke cognitive decline or dementia
Blood pressure treatment

We cannot recommend intensive treatment of blood pressure compared to usual care solely for the prevention of post-stroke cognitive decline and dementia.

Quality of evidence: Very Low

(This recommendation only relates to cognitive effects of blood pressure treatment)

Rationale

**PICO question:** In people with a history of stroke, does monitored intensive management of vascular risk factors, compared to usual care, prevent future cognitive decline or dementia?

**Analysis of current evidence**

The intervention of interest was 'intensive' management of traditional cardiovascular risk factors. Intensive management was defined as treatment of cardiovascular risk factors beyond what would be expected as standard practice at the time of the study. The two likely models of intervention we anticipated were, intervention(s) to reach treatment targets that are more aggressive than described in contemporary guidelines and/or intervention(s) to reach guideline targets in populations where these targets are not reached. As with other PICOs in this section, we pre-specified that we would only include randomised controlled trials (RCTs) and required a minimum of 50 participants per arm.

The literature search identified five RCTs, comparing the management of three different vascular risk factors. In our Summary of Findings table (Table 2) we assess the evidence for intensive treatment in aggregate. In the text below, we also consider three pharmacological interventions individually.

**Hypertension.** Four RCTs investigated the effect of intensive vascular management of hypertension on dementia and cognitive decline; three studies compared antihypertensive treatment: nimodipine in preventing cognitive impairment in ischemic cerebrovascular event [20] (NICE, 30mg three times daily), Prevention Regimen for Effectively Avoiding Second Strokes [21] (PRoFESS, telmisartan 80mg daily), Perindopril Protection Against Recurrent Stroke Study [22] (PROGRESS, perindopril 4mg daily ± indapamide 2.5mg daily) with placebo. One study compared two different blood pressure targets (Secondary Prevention of SubCortical Stroke Study [23] (SPS3; <130mmHg vs 130-149 mmHg, open-label)) in patients with recent lacunar stroke. These trials recruited respectively 654, 3020, 20,332, and 6105 patients (30111 in total; 15018 intervention, 15093 control group), with a history of stroke. Three studies only included participants with a recent ischemic stroke (NICE < 7 days, SPS3, <6 months; PRoFESS, <90 days), one study included participants with a history of stroke (ischemic and haemorrhagic, no subarachnoid haemorrhage) in the previous 5 years (PROGRESS). The risk of bias in each trial was considered low (Supplementary Materials).

There was no effect of antihypertensive treatment vs placebo on dementia incidence (pooled OR: 0.96 (95%CI: 0.86-1.08); 2 studies (PRoFESS, PROGRESS); 23375 participants; Figure 1) nor was there an effect of blood pressure reduction on incident mild cognitive impairment (MCI) (OR:0.94 (95% CI: 0.80 - 1.10); 1 study). Operationalisation of cognitive decline was heterogeneous. Three studies did not find an effect of intensive blood pressure management on cognitive decline (NICE, ADAS-Cog ≥4 point decrease since baseline OR:0.93(95% CI: 0.80 - 1.10); SPS3, between group mean difference (MD) 0.25 Cognitive Assessment Screening Instrument (CASI), p=0.520; PRoFESS, MMSE <25 OR:0.95 (95%CI:0.86 - 1.05)). For two studies only (NICE, PROGRESS; 6683 participants), there was a modest effect of antihypertensive treatment on prevention of cognitive decline, when operationalised as ≥3 points drop in MMSE score at end of study follow-up (pooled OR:0.79 (95%CI: 0.67-0.94); Figure 2). While this result is encouraging, it is not completely aligned with our specified outcomes and the lack of treatment effect for dementia and MCI leads to serious concerns over inconsistency.

**Antithrombotic therapy.** One RCT investigated the effect of short-term dual antiplatelet treatment on cognitive function in patients with a recent (<6 months) lacunar infarction (SPS3 [24], aspirin 325 mg plus clopidogrel 75 mg vs aspirin 325 mg plus placebo), including 3020 participants in total. The risk of bias in this study was considered low (Supplementary Materials). This study did not find an effect of dual antiplatelet therapy on MCI incidence (OR: 0.94 (95%CI:0.81 – 1.10)) or cognitive decline (between group mean difference (MD) 0.14 CASI points, p=0.858). However, risk of bleeding was increased.

**Statin treatment.** One RCT investigated the effect of 10mg pravastatin vs placebo on dementia incidence and cognitive impairment assessed by the clinical dementia rating (CDR) and MMSE in 1578 participants. [25] As statin therapy is now considered standard following ischaemic stroke, it is debatable whether this intervention represents intensive risk factor modification. The risk of bias in this study was considered low (Supplementary Materials). In this study, there was no effect of the intervention on dementia incidence (risk difference 0.10%, p=0.94) or cognitive decline (CDR between group mean difference (MD) -0.1, p=0.53; MMSE between group MD:0.2 (p=0.18)).

European Stroke Organisation (ESO) and European Academy of Neurology (EAN) Joint Guidelines on post-stroke cognitive impairment - European
Statin treatment

We cannot recommend intensive statin treatment compared to usual care solely for the prevention of post-stroke cognitive decline or dementia.

Quality of evidence: Very Low

(This recommendation only relates to cognitive effects of statin treatment)

Rationale

PICO question: In people with a history of stroke, does monitored intensive management of vascular risk factors, compared to usual care, prevent: future cognitive decline or dementia?

Analysis of current evidence

The intervention of interest was ‘intensive’ management of traditional cardiovascular risk factors. Intensive management was defined as treatment of cardiovascular risk factors beyond what would be expected as standard practice at the time of the study. The two likely models of intervention we anticipated were, intervention(s) to reach treatment targets that are more aggressive than described in contemporary guidelines and/or intervention(s) to reach guideline targets in populations where these targets are not reached. As with other PICOs in this section, we pre-specified that we would only include randomised controlled trials (RCTs) and required a minimum of 50 participants per arm.

The literature search identified five RCTs, comparing the management of three different vascular risk factors. In our Summary of Findings table (Table 2) we assess the evidence for intensive treatment in aggregate. In the text below, we also consider three pharmacological interventions individually.

Hypertension. Four RCTs investigated the effect of intensive vascular management of hypertension on dementia and cognitive decline; three studies compared antihypertensive treatment: nimodipine in preventing cognitive impairment in ischaemic cerebrovascular event[20] (NICE, 30mg three times daily), Prevention Regimen for Effectively Avoiding Second Strokes[21] (PROFESS, telmisartan 80mg daily), Perindopril Protection Against Recurrent Stroke Study[22] (PROGRESS, perindopril 4mg daily ± indapamide 2.5mg daily) with placebo. One study compared two different blood pressure targets (Secondary Prevention of SubCortical Stroke Study[23] (SPS3; <130mmHg vs 130-149 mmHg, open-label)) in patients with recent lacunar stroke. These trials recruited respectively 654, 3020, 20,332, and 6105 patients (30111 in total; 15018 intervention, 15093 control group), with a history of stroke. Three studies only included participants with a recent ischemic stroke (NICE < 7 days, SPS3, <6 months; PROFESS, <90 days), one study included participants with a history of stroke (ischemic and haemorrhagic, no subarachnoid haemorrhage) in the previous 5 years (PROGRESS). The risk of bias in each trial was considered low (Supplementary Materials).

There was no effect of antihypertensive treatment vs placebo on dementia incidence (pooled OR: 0.96 (95%CI: 0.86-1.08); 2 studies (PROFESS, PROGRESS); 23375 participants; Figure 1) nor was there an effect of blood pressure reduction on incident mild cognitive impairment (MCI) (OR:0.94 (95%CI: 0.80 - 1.10); 1 study).
heterogeneous. Three studies did not find an effect of intensive blood pressure management on cognitive decline (NICE, ADAS-Cog ≥4 point decrease since baseline OR:0.93(95%CI: 0.52–1.66); SPS3, between group mean difference (MD) 0.12 Cognitive Assessment Screening Instrument (CASI), p=0.520; PROFESS, MMSE <25 OR:0.95 (95%CI:0.86 - 1.05)). For two studies only (NICE, PROGRESS: 6683 participants), there was a modest effect of antihypertensive treatment on prevention of cognitive decline, when operationalised as ≥3 points drop in MMSE score at end of study follow-up (pooled OR:0.79 (95%CI: 0.67-0.94); Figure 2). While this result is encouraging, it is not completely aligned with our specified outcomes and the lack of treatment effect for dementia and MCI leads to serious concerns over inconsistency.

**Antithrombotic therapy.** One RCT investigated the effect of short-term dual antiplatelet treatment on cognitive function in patients with a recent (<6 months) lacunar infarction (SPS3[24], aspirin 325 mg plus clopidogrel 75 mg vs aspirin 325 mg plus placebo), including 3020 participants in total. The risk of bias in this study was considered low (Supplementary Materials). This study did not find an effect of dual antiplatelet therapy on MCI incidence (OR: 0.94 (95%CI:0.81 – 1.10)) or cognitive decline (between group mean difference (MD) 0.14 CASI points, p=0.858). However, risk of bleeding was increased.

**Statin treatment.** One RCT investigated the effect of 10mg pravastatin vs placebo on dementia incidence and cognitive impairment assessed by the clinical dementia rating (CDR) and MMSE in 1578 participants.[25] As statin therapy is now considered standard following ischaemic stroke, it is debatable whether this intervention represents intensive risk factor modification. The risk of bias in this study was considered low (Supplementary Materials). In this study, there was no effect of the intervention on dementia incidence (risk difference 0.10%, p=0.94) or cognitive decline (CDR between group mean difference (MD) -0.1, p=0.53; MMSE between group MD:0.2 (p=0.18)).

Consensus recommendation

Given the beneficial effects of vascular risk management on prevention of recurrent stroke and cardiovascular disease, comprehensive risk factor management including blood pressure reduction, antithrombotic and statin is warranted following stroke, even though the cognitive benefits are unclear.

Targets for stroke risk factor management are constantly evolving and approaches that were historically considered ‘intensive’ are now common practice and recommended in guidelines.

Future trials of secondary prevention in stroke should include cognitive outcome measures.

8.3 Monitored multicomponent interventions (lifestyle and pharmacological) for the prevention of poststroke cognitive decline or dementia

We cannot recommend multicomponent interventions (including medications and lifestyle interventions) solely for the prevention of post-stroke cognitive decline or dementia.

Quality of evidence: Very Low ⊗

(This recommendation only relates to the cognitive effects of multicomponent interventions)
Rationale

**PICO question:** In people with a history of stroke, do monitored multicomponent interventions (lifestyle and pharmacological), compared to usual care, prevent: future cognitive decline or dementia?

*Analysis of current evidence*

The intervention of interest was multicomponent interventions, defined as intervention that include more than one potentially active treatment and that are not limited to drug therapy alone. As with other PICOs in this section, we pre-specified that we would only include randomised controlled trials (RCTs) as observational data in the field are prone to many biases. We also pre-specified that trials would require a minimum of 50 participants per arm, because we felt as a writing group that smaller trials are unlikely to show an effect. At the time of setting the PICO questions, we anticipated that multicomponent intervention RCTs would be distinct from the lifestyle or vascular risk factor intervention studies reviewed in previous sections. However, there was considerable overlap.

The literature search identified one relevant RCT comparing a monitored multicomponent intervention with care as usual for the prevention of cognitive decline after stroke. This study also met criteria for PICO 1 and is fully assessed in that section. We did not identify any literature on the prevention of dementia.

The ASPIS study[10] included 202 participants (101 intervention, 101 control group) aged 40 to 80 years with a clinical diagnosis of ischemic stroke within the previous 3 months. The intervention consisted of intensive management and motivation for compliance with clinical therapy, adequate blood pressure, lipid and glycaemic control, healthy diet, regular physical activity, and cognitive training. This study found no benefit of 24-month multidomain intervention on the incidence of post-stroke cognitive decline in comparison with standard stroke care (RR (95%CI) 0.87 (0.36-2.10)). There were no data on the clinical outcome of incident dementia and so we felt there were issues with indirectness and this is reflected in the GRADE assessment.

Findings are summarised in table 3. We downgraded the evidence on prevention of cognitive decline to low quality evidence for imprecision, as the effect came from one single study and the confidence intervals included both beneficial as harmful effects.

*Additional Information*

We found limited evidence on the effectiveness of multicomponent interventions for the prevention of cognitive decline and dementia in post-stroke patients. The evidence is in line with several large multicomponent intervention studies in the general population that did not find an effect on dementia incidence or cognitive decline.[28][29] However, there are other reasons why risk factor modification (both lifestyle and pharmacological) is still warranted after stroke, such as secondary stroke and cardiovascular disease prevention.

**Consensus recommendation**

All but one of the writing group agreed that:

Monitored multicomponent interventions, cannot be recommended for the prevention of cognitive decline or dementia following stroke alone, but there are other potential health benefits associated with these lifestyle interventions, such as the prevention of future cardiovascular disease or recurrent stroke.

8.4 Cognitive training for the prevention of poststroke cognitive decline and dementia

There is continued uncertainty over the benefits and limitations of cognitive training for the prevention of cognitive decline and dementia in people living with stroke.

**Quality of evidence:** Very Low ⊗

**Rationale**

*Analysis of current evidence*

The intervention of interest was cognitive training, which could include both electronic/computerised training and more traditional pen-and-paper based training platforms. We used the definition of cognitive training developed for Cochrane reviews in the field: ‘Cognitive training involves guided practice on a set of standardized tasks designed to reflect particular cognitive
functions, such as memory, attention, or problem solving.[30] As with other PICOs in this section, we pre-specified that we would only include randomised controlled trials (RCTs) and required a minimum of 50 participants per arm. Finally, we pre-specified that duration of follow-up should be at least six months to demonstrate convincing sustained cognitive benefit.

The literature search did not identify any suitable RCT directly addressing this PICO question i.e. we found no RCT investigating cognitive training as the sole intervention and including more than 50 participants per group over a period longer than 6 months.

**Additional Information**

A number of trials of cognitive training with sample sizes and intervention periods less than our pre-specified thresholds are available and are summarized in various reviews.[31][32] In general, trials of cognitive training in stroke have reported low quality evidence for small beneficial effects. Trials generally investigated the effects of cognitive training for remediation of cognitive impairments, rather than our outcomes of interest of cognitive decline or dementia. In general, outcomes were assessed shortly after intervention and benefits demonstrated may be smaller than a minimal clinically important difference. Trials mainly targeted single cognitive domain deficits such as aphasia and neglect and are less relevant to our PICO question of global prevention of cognitive decline. We refer to the section of this guideline on treatment for a discussion of the evidence on cognitive rehabilitation for prevalent cognitive impairments.

Several recent reviews have investigated the effect of cognitive training in healthy older adults or in people with mild cognitive impairment and have been summarized in an overview by Gavelin.[33] Meta-analysis reported effect sizes ranging from Hedges' $g = 0.13$ to 0.64 in healthy adults (19 reviews) and from $g = 0.32$ to 0.60 in people with mild cognitive impairment (5 reviews), favouring cognitive training compared to active or passive control groups. The quality of evidence ranged from critically low to medium. Sample sizes of most studies were small to medium, and only few trials had follow-up periods longer than 6 months or reported dementia incidence. It is unclear if these benefits translate into a sustained effect of prevention of dementia. It is also debatable whether evidence from healthy older adults can inform post-stroke care. People living with stroke, especially those with stroke related impairments, may need more adaptations of cognitive training interventions.

Observational studies suggest that education, cognitively stimulating activity and social interactions can protect against cognitive decline and dementia.[34][35][36] These associations have also been observed in stroke cohorts.[37][38] However, we must be wary of making causal inferences. Although not within the scope of our PICO, an RCT of 103 patients admitted to a neurorehabilitation ward (51% stroke) reported that patients offered enriched activities had larger improvements in cognitive scores at discharge and 3 months than a control group offered usual ward-based activities.[39]

### Clinical Question/ PICO

- **Population:** People with a history of stroke
- **Intervention:** Cognitive training
- **Comparator:** Usual care

#### Consensus recommendation

All but one of the writing group agreed that:

Cognitive training could be considered following stroke as part of a broader rehabilitation package. However, based on the current available literature, there is no evidence that cognitive training, as a single intervention, has a clinically meaningful or sustained benefit for prevention of cognitive decline or dementia following stroke.

### 8.5 Stopping pharmacological management of vascular risk factors (de-prescribing) for the prevention of poststroke cognitive decline and dementia
There is continued uncertainty over the benefits and risks of continuing treatment with antihypertensive or statin medications compared to withdrawal of these medications for cognitive or quality of life outcomes in people living with post-stroke dementia.

Quality of evidence: Very Low

Rationale

**PICO question:** In people with a history of post-stroke dementia does, stopping pharmacological management of vascular risk factors (de-prescribing), compared to continuing these medications prevent: future cognitive decline or improve health related quality of life?

**Analysis of current evidence**

For this PICO the population of interest and focus are different to the other PICO questions in this section. Here, we are concerned with people living with a post-stroke cognitive syndrome and the intervention is stopping existing medication rather than starting a new medication. We separately considered blood pressure management and statins. As with other PICOs in this section, we pre-specified that we would only include randomised controlled trials (RCTs) and required a minimum of 50 participants per arm.

Pharmacological treatment of vascular risk factors is an important strategy to prevent recurrent stroke and cardiovascular disease following stroke. As vascular risk factors and associated (cerebro-)vascular disease are related to cognitive impairment/dementia, control of hypertension and dyslipidaemia is generally recommended for dementia prevention. A recent European Academy of Neurology guideline on medical management of dementia suggested this advice should also apply to people living with mild-moderate dementia.[40] For people with severe dementia and anticipated short life expectancy the risk-benefit of managing vascular risk is less clear. Pharmacological treatment of vascular risk factors is associated with adverse effects and could potentially have a detrimental impact on cognition. For example, antihypertensive drugs hypothetically increase the risk of cerebral hypoperfusion that could worsen cognition.

Our literature search did not identify any RCT on the cognitive effect of withdrawal of antihypertensive medication in people with post-stroke dementia. There were RCTs describing antihypertensive withdrawal in people living with dementia and stroke and these are considered in the Additional Information section below. The literature search did not identify any RCT on the cognitive effect of statin withdrawal in people with post-stroke dementia or undifferentiated dementia.

**Additional information**

**Antihypertensive withdrawal:** we found two RCTs describing antihypertensive drug withdrawal and cognitive effects, these did not fulfil our selection criteria. One trial only investigated stopping of pre-existing antihypertensives in the acute phase (first seven days) of stroke.[41] The other trial recruited older adults with mild cognitive impairment but free of stroke.[42] Both studies assessed only short-term cognitive outcomes (three months and 16 weeks, respectively). A Cochrane meta-analysis on antihypertensive deprescribing concluded that there is insufficient evidence regarding the effect of antihypertensive drug withdrawal on cognitive function and prevention of dementia.[43]

A prospective observational study evaluated whether discontinuation of antihypertensive medication was associated with memory complaints or incident dementia in community-dwelling older people (70-78 years) during 6-8 years of follow-up.[44] Of 1451 participants with available follow-up information, 85 stopped antihypertensive medication. Dementia occurred more often in the discontinuation group (13.4% vs 6.2%, P=0.02), while mortality was similar (16.5% vs 13.9%, P=0.52). Antihypertensive discontinuation was not associated with change in subjective memory complaints. Notably, around roughly 15% of included participants had a history of stroke. The theoretical concern over antihypertensives causing harmful cerebral hypoperfusion is not consistently proven, for example in an RCT of 62 people with cerebrovascular small vessel disease intensive blood pressure lowering did not significantly reduce cerebral perfusion.[45]

**Statin withdrawal:** There is a very limited literature on the effects of statin withdrawal. A 2016 Cochrane review on statin withdrawal in patients with dementia found no suitable studies addressing this question.[46] Notably, in an RCT on statin withdrawal in patients with a short life expectancy of less than one year, without a recent history of cardiovascular disease, (22% were cognitively impaired), patients in the discontinuation group had slightly improved quality of life.[47]

**Clinical Question/ PICO**

- **Population:** People with a history of stroke
- **Intervention:** Stopping pharmacological management of vascular risk factors (de-prescribing)
Routine cognitive screening for the prevention of poststroke cognitive decline or dementia

Due to a lack of relevant trials in patients with stroke, there is continued uncertainty over the benefits and risks of routine cognitive screening to improve stroke care.

Quality of evidence: Very Low ⊕

(This recommendation applies only to routine screening of all patients presenting with stroke, and does not apply to clinician directed assessment)

Rationale

PICO question: In patients with stroke (acute or post-acute), what is the accuracy of Montreal Cognitive Assessment for contemporaneous diagnosis of post-stroke cognitive impairment or dementia?

Analysis of the current evidence

In this PICO we consider cognitive assessment, in particular short screening tests, following stroke as an intervention, i.e. does routine screening of stroke survivors improve outcomes. For the purposes of this PICO, we considered any point in the stroke pathway. However, we were particularly interested in cognitive screening performed in the acute setting as such screening is recommended in many international stroke best practice statements and clinical guidelines.[48] Our intention was not to assess the benefits of clinician directed, targeted cognitive assessment, but rather to assess policies of routine, standardised screening of all stroke survivors. For consistency of language, we differentiate screening from more comprehensive assessments or diagnostic formulations.

We pre-specified three questions with separate outcomes of interest, (1) does cognitive screening increase the detection of later cognitive syndromes in clinical practice?; (2) does cognitive screening change subsequent care pathways? and (3) does cognitive screening translate into health economic benefits? For this PICO, we only considered studies that used randomised or quasi-randomised trial designs.

Although there are many papers describing the diagnostic properties of cognitive screening tools in stroke, we found relatively few papers that assessed whether this cognitive screening made a difference to patient care pathways or outcomes. We found no trials that described outcomes relating to diagnosis or the components of stroke care. One study (Forster 2009)[49] assessed resource use as a secondary outcome and is considered further in the additional information section, but as this study used a multi-component assessment strategy that could include, but did not mandate, cognitive screening, it does not meet our PICO inclusion criteria.

Additional Information

We found four trials that were relevant to the topic but not completely aligned with our original question. The trials had
differing populations, interventions, and outcomes, so we did not attempt a quantitative summary. The trials had similar methodological limitations and highlight the difficulty in trials of cognitive screening. As stroke-survivor participants had to provide informed consent and had to be able to complete the relevant assessments, included populations were not representative of unselected stroke survivors. There were issues with attrition, for example in the OCS CARE trial\[50\], 821 were randomised but outcomes were only available for 467 (57%). All the trials were under-powered to detect small, but meaningful differences in important secondary outcomes like care-giver burden or satisfaction with care.

The OCS CARE trial\[50\] randomised post-acute stroke-survivors to domain specific cognitive screening using the Oxford Cognitive Screen (OCS) or general cognitive screening using the Montreal Cognitive Assessment (MoCA). At six months there was no difference in stroke impairments, or health related quality of life.

McKinney et al\[51\] randomised 228 four-week, stroke-survivors to a bespoke, staged neuropsychological battery or usual cognitive screening. At six months there was no difference in function, mental health, or satisfaction with care, although there was a trend towards reduced care-giver strain.

Forster et al\[49\] randomised 265 stroke-survivors at three months to a bespoke assessment package that was not exclusively focused on cognition but could include cognitive assessment where indicated. At one year follow-up there was no improvement in function, but a trend towards improvement in secondary outcomes of care-giver strain, satisfaction with care and healthcare costs.

Arts et al\[52\] described a pilot of an outpatient physical and cognitive testing program for minor stroke. Of 42 recruited, 38 received the intervention and reported increased satisfaction but no difference in measures of function, mood or quality of life.

We found a protocol for an ongoing trial (ECO-stroke)\[53\] of a multicomponent assessment administered when stroke survivors return home. The study will include measures of clinical effectiveness, cost-effectiveness and process evaluation.

In assessing the evidence for this PICO question and for the other diagnosis themed PICO questions in this guidance, there are certain contextual factors that require consideration. When cognitive testing is used it can have differing purposes. For example, in acute stroke care a brief assessment can inform whether a person is at risk of cognitive problems and likely to require more detailed cognitive assessment later in the admission. This could be termed cognitive triage, or screening and screening is the term preferred in this guidance. A more detailed assessment may be used to inform a diagnostic formulation, this process is often referred to as cognitive assessment. In research, cognitive tests may be used as outcome measures, a process that is neither screening nor assessment.

This PICO did not consider neuropsychological assessment which allows for a comprehensive characterisation of cognitive strengths and weaknesses, emotional and behavioural changes post-stroke, and biopsychosocial case formulation to inform a range of management recommendations and treatment pathways.

For our PICO we included those outcomes rated as critical by the writing group. As cognitive screening is a system based intervention, we prioritised outcomes at the population level. We recognise that we did not include directly patient focussed outcome measures such as acceptability and feasibility, but these would be important considerations for any cognitive screening program.

The preferred properties of a cognitive test will differ depending on the purpose of that test. For example, in the case of a brief screening tool where a positive result may trigger a more detailed assessment, it could be argued that the imperative is to detect as many people with possible cognitive problems as possible even if this risks unnecessary additional testing for some. In this case sensitivity may be preferred over specificity.

Related to this point, the potential consequences of a false positive and false negative diagnosis should also be considered. The implications of missing prevalent cognitive issues (false negative) could include not being referred for treatment. Whereas wrongly labelling a person as having cognitive issues risks worry and further unnecessary testing. The balance of harms will vary in differing healthcare settings and it is difficult to be prescriptive when offering general guidance.
**Rationale**

**PICO question:** In patients with stroke (acute or post-acute), what is the accuracy of Montreal Cognitive Assessment for contemporaneous diagnosis of post-stroke cognitive impairment or dementia?

**Analysis of the current evidence**

For this PICO, and subsequent PICOs in this Diagnosis section, we will describe accuracy of tests rather than efficacy and we will focus on those cognitive screening tools prioritised by the module writing group. We will use the terminology favoured in test synthesis literature\[54\] i.e. ‘diagnostic test accuracy’, but we recognise that the tools we describe are not diagnostic in their own right. While we refer to these questions using the PICO terminology, our questions on screening tools are considering accuracy rather than comparative efficacy of interventions, so in formulating these questions our concepts of interest were the index test (screening tool), reference standard and condition of interest (in this case post-stroke cognitive impairment or dementia).

In clinical practice, a cognitive screening tool is usually used, directly or indirectly, to inform a management decision. For example, a person with recent stroke who scores poorly on a multi-domain screening tool may be referred for more detailed assessment that will guide subsequent rehabilitation.\[55\] However, PICO 6 has shown that there is limited evidence around the test-treatment-outcome paradigm for cognitive testing in stroke. Therefore, to help the clinician choose the most appropriate assessment for a given clinical context, an analysis of the test’s properties with a focus on metrics such as sensitivity and specificity can be useful.\[56\]

The methods underpinning the test accuracy synthesis differ in some regards from the standard synthesis of trials. In particular, the application of GRADE to diagnostic test accuracy is not as well developed as it is for synthesis of intervention studies. In our GRADE assessment we considered risk of bias and applicability using the QUADAS-2 tool\[57\], we considered internal consistency through visual inspection of forest plots and considered the precision of the summary estimate. More detailed descriptions of test accuracy synthesis and reporting are available from Cochrane\[58\] and others.

The Montreal Cognitive Assessment (MoCA) is a brief screening tool used to detect mild cognitive impairment and dementia and has been used extensively across research settings and clinical groups, including stroke survivors.\[59\] MoCA assesses a number of cognitive domains, including executive function, memory, attention, language, and orientation to provide a test score of global cognitive function. However, the MoCA has been criticised due to the necessity of intact visuospatial and language function to complete the assessment.\[60\]
We identified 17 studies\cite{61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77} that assessed the diagnostic test accuracy of the MoCA across a number of settings (e.g., acute, rehabilitation, outpatient, community) in a stroke population. Stroke aetiology was mixed (9 studies), ischaemic (7 studies), or not reported (1 study). The time since stroke onset varied considerably across studies, from <2 days to >12 months. The reference standard was clinical diagnosis of post-stroke cognitive impairment/dementia in 5 studies, cognitive impairment as defined by a neuropsychological test battery (11 studies), or both (1 study).

We performed meta-analyses to give summary estimates of the sensitivity and specificity, using bespoke software.\cite{78} It should be noted that across studies, test properties were described at varying cut-offs of the assessment scale and our summary estimates are for those cut-offs points that were most common across studies. The majority of papers had a high risk of bias. Limitations included non-consecutive sampling of stroke survivors, study heterogeneity, and unblinded interpretation of either the index test or reference standard. Similarly, little information was provided on incomplete or missing data (Supplementary Materials).

We recognise that using screening tool threshold scores to make a cognitive classification is a reductionist approach. At the individual patient level, scores should be interpreted in the context of education, cultural background, language, and many other factors. However, the threshold score approach is commonly used in practice and research and so we assessed the test properties of MoCA at varying thresholds.

Our summary analyses suggest a common pattern of test properties for the MoCA when used in a stroke population with sensitivity favoured over specificity. Table 4 shows our GRADE assessment of the diagnostic accuracy of MoCA for contemporaneous diagnosis of post-stroke cognitive impairment. Across 17 studies, using the best fit sensitivity and specificity threshold if more than one threshold was reported and irrespective of the timeframe of cognitive screening, sensitivity was 0.84 and specificity was 0.71 (see Figure 3). At the lower MoCA threshold of 21-23 sensitivity was 0.84 and specificity 0.78. A higher cut-off of 24-26 has similar sensitivity of 0.86 but somewhat lower specificity of 0.59. For initial screening of cognition, these properties could be considered acceptable, however the MoCA is not a substitute for clinical diagnostic assessment.

While sensitivity was consistent across the reported cut-off points, specificity was lower for the higher cut-off of 24-26, suggesting that the lower MoCA cut-off of 21-23 has improved overall test properties for post-stroke cognitive impairment. Similarly, our analysis suggests that the MoCA has better diagnostic test accuracy when used in the post-acute (>3 months post-stroke) than acute phase. However, there was a common issue across studies of inappropriate exclusion of patients with moderate/severe aphasia or of those who lack the ability to consent, which leaves potential for bias. Therefore, we recommend due caution in the interpretation of these findings.

**Additional Information**

Diagnostic test accuracy of the MoCA in stroke has been the subject of a number of systematic reviews. Lees et al.\cite{79} reviewed the test accuracy of various cognitive screening tools for dementia or multi-domain cognitive impairment after stroke. In examining the MoCA, pooled data from 6 studies which used the cut off <22/30 reported sensitivity 0.84 and specificity 0.78. A higher cut-off (<26/30) had a lower specificity of 0.45 but a higher sensitivity of 0.95. These results are broadly in keeping with our synthesis, albeit our more contemporary review has a greater number of studies included.

Reviews of MoCA in non-stroke settings are available and the pattern of higher sensitivity and lower specificity is consistent across studies.\cite{80} It should be remembered that the MoCA was developed to assess for mild cognitive impairment in community dwelling older adults and was not originally intended for use in acute stroke. There is a literature describing issues with feasibility of assessment when MoCA is applied in the acute stroke setting.\cite{81} Non-cognitive impairments can compromise completion of the MoCA and research teams have adopted various approaches to handling partial or fully incomplete MoCA assessments.\cite{74} A recent development with application of MoCA is the need for mandatory training with associated training costs. It remains to be seen whether this will change the patterns of MoCA use in practice and research.
8.8 Accuracy of Folstein's Mini-Mental State Examination for contemporaneous diagnosis of dementia

There are inherent limitations to the Montreal Cognitive Assessment (MoCA), which relies on intact visuospatial and language function for completion.

While the MoCA has acceptable test properties for use as an initial screening test in a stroke population, consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the MoCA cognitive screening test should be fully trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive MoCA test result and findings should be shared with the stroke care team.

We suggest that in acute and post-acute stroke settings, screening of cognition using Folstein's Mini-Mental State Examination (MMSE) be considered. MMSE should not be used as a substitute for comprehensive clinical assessment.

At the conventional threshold for test positivity, MMSE screening will exclude most stroke survivors with no important cognitive issues, but at the cost of substantial false negatives.

Rationale

**PICO question:** In patients with stroke (acute or post-acute), what is the accuracy of Folstein's Mini-Mental State Examination for contemporaneous diagnosis of dementia?

**Analysis of current evidence**

In this PICO question we describe the accuracy of Folstein's Mini Mental State Examination (MMSE) when used in the stroke context. The synthesis of test accuracy data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 7.

MMSE was developed as a screening test for dementia over 40 years ago and has also been widely used as an outcome measure in therapeutic studies. It consists of a number of items, with total possible score of 30, covering domains of orientation, memory, and praxis. MMSE has been criticised because it does not assess executive function or language in detail.

We found 16[62][63][64][70][71][74][75][84][85][86][87][88][89][90][91][92] studies that had assessed the test accuracy of MMSE, 6 against a clinical diagnosis, 10 against a neuropsychological test battery with the reference standard being dementia (4 studies), cognitive impairment (9 studies), or both (2 studies). Stroke aetiology was mixed (9 studies), ischaemic (5 studies), or not reported (2 study). Study setting varied and included acute inpatient, outpatient, community, and rehabilitation services. Time since stroke was also variable between studies, ranging from less than 7 days to over a year and study size ranged from 51 to 300.

Using the QUADAS-2 tool[57], we found that all papers had a high risk of bias. Limitations included non-consecutive sampling of stroke survivors, study heterogeneity, handling of missing data, and unblinded interpretation of either the index test or reference standard (Supplementary Materials).

We performed meta-analyses to give summary estimates of the sensitivity and specificity. It should be noted that across studies, test properties were described at varying cut-offs of the assessment scale and our summary estimates are for those cut-offs
points that were most common across studies. The need for caution in applying standardised thresholds at the individual patient level were discussed in PICO 7 and also apply here.

Table 5 shows the summary estimates of sensitivity and specificity. Across 16 studies, using the best fit sensitivity and specificity threshold if more than one threshold was reported and irrespective of the timeframe of cognitive screening, sensitivity was 0.73 and specificity was 0.62 (see Figure 4). At the standard MMSE thresholds of 22-24 sensitivity was 0.68 and specificity 0.82. Higher cut-offs of 25-27 had similar performance with marginally lower specificity (sensitivity 0.70 and specificity 0.76).

Sensitivity and specificity clearly varied according to the cut-off chosen, but there was a consistent picture of generally higher specificity but lower sensitivity, with sensitivity slightly higher and specificity lower for acute rather than chronic time periods. Despite the clinical heterogeneity and potential bias issues, studies gave consistent findings across several settings.

**Additional information**

The MMSE has been the focus of previous reviews, for example Lees et al (2014)[79] reviewed cognitive screening tests for dementia or multi-domain cognitive impairment after stroke, based on a literature search in Jan 2014. They pooled data from 12 studies which used the MMSE and with cut-off <27/30 reported sensitivity 0.88 and specificity 0.62. A lower cut-off (<25/30) had lower sensitivity but higher specificity (0.71 and specificity 0.85).

Diagnostic test accuracy reviews and meta-analyses of MMSE are available for non-stroke populations.[93][94] Test accuracy metrics are broadly similar to those reported in our stroke analysis. These reviews conclude that MMSE may have utility for assessing possible dementia but is less useful for assessing for mild cognitive impairment. Even for the assessment of dementia, MMSE is imperfect and not a substitute for detailed clinical assessment.

Most test accuracy analyses have considered screening tools in isolation. This is partly because of the lack of studies comparing two test strategies in the same population. For the clinician faced with multiple test options, the question of importance is often ‘which test is better’. A recent review used a network approach to indirectly rank the test properties of MoCA and MMSE in the stroke setting. Using this approach, MoCA at threshold <26/30 appeared to have the best true positive rate, whereas MMSE at threshold <25/30 appeared to have the best true negative rate.[95] The most appropriate test in a particular situation will depend on the relative consequences of false positive and false negative screening results.

The MMSE has similar feasibility issues as described for the MoCA, particularly with regards to acute assessment when a patient is unwell or has stroke related impairments.[60] MMSE has copyright restrictions and is not free to use for all, some centres no longer use the test routinely for this reason.

---

**Consensus recommendation**

There are inherent limitations to the Mini Mental State Examination (MMSE), which relies on intact visuospatial and language function for completion.

While the MMSE has acceptable test properties for use as an initial screening test in a stroke population, consideration should be given to the development of cognition screening tools that are more acceptable and feasible for those with communication difficulties or spatial neglect.

Those utilising the MMSE cognitive screening test should be fully trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive MMSE test and findings should be shared with the stroke care team.

---

**8.9 Accuracy of Addenbrooke's Cognitive Examination (ACE) for contemporaneous diagnosis of dementia**
We suggest that in acute and post-acute stroke settings, screening of cognition with one of the versions of the Addenbrooke's Cognitive Examination (ACE) can be considered. ACE should not be used as a substitute for comprehensive clinical assessment.

Test properties are sensitive to the threshold used to define test positivity, but there were insufficient data to make recommendations around the optimal cut-off for use in stroke.

Quality of evidence: Very Low ☹️

Rationale

**PICO question:** In patients with stroke (acute or post-acute), what is the accuracy of Addenbrooke's Cognitive Examination (ACE) for contemporaneous diagnosis of dementia?

**Analysis of the current evidence**

In this PICO question we describe the accuracy of the various iterations of the Addenbrooke's Cognitive Examination (ACE) when used in the stroke context. The synthesis of test accuracy data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 7.

The Addenbrooke's cognitive examination (ACE) was originally developed to overcome some of the recognised limitations of the MMSE by being more sensitive to mild dementia and able to differentiate between dementia subtypes, specifically Alzheimer's disease and fronto-temporal dementia. Subsequent adaptations of the ACE include the Addenbrooke's Cognitive Examination-Revised (ACE-R) and ACE-III.

The ACE has 21 questions, covering five different cognitive domains: attention/orientation, memory, language, verbal fluency, and visual perceptual/visuospatial skills. The total score is 100, and the thresholds used to diagnosis dementia are typically 82/83 or 88.

We found four studies that assessed the accuracy of versions of the ACE in stroke, two used clinical diagnosis and two used a neuropsychological test battery with reference standard being dementia (1 study) or cognitive impairment (3 studies). The four studies identified varied in study setting and included acute inpatient, community, and rehabilitation services. Time since stroke was variable between studies, ranging from less than 18 days to >12 months and study size ranged from 18 to 91.

Using the QUADAS-2 tool, we found that all studies had high risk of bias. Limitations included study heterogeneity, unblinded interpretation of either the index test or reference standard, and handling of missing data. (Supplementary Materials)

Given the heterogeneity in test content, application, scoring, and setting we did not attempt a meta-analysis of ACE test accuracy data. Table 6 describes the sensitivity and specificity of the four studies for a range of thresholds. Sensitivity and specificity varied across studies and according to the threshold chosen, with sensitivity being higher and specificity lower for higher thresholds. The need for caution in applying standardised thresholds at the individual patient level were discussed in PICO 7 and also apply here. Our overall GRADE assessment was of very low quality of evidence due to heterogeneity, inconsistency, imprecision, and risk of bias.

**Additional information**

There are reviews of the test properties of various iterations of ACE in non-stroke settings. The most recent review reports a limited literature on the accuracy of the newer versions of the test. Where data are available, there is a pattern of sensitivity and specificity varying across studies and thresholds used to define test positive results, with sensitivity being higher and specificity lower for higher thresholds. These results are similar to those seen in our stroke accuracy synthesis.

There is less published literature on feasibility and acceptability of ACE based assessment in stroke settings. The ACE is a longer test than MMSE and MoCA although offers a more detailed assessment, thus it would not seem suitable for use in a time pressured acute environment. In one of the papers that included both ACE and MoCA, the ACE had a longer administration time, but this did not improve the accuracy compared to MoCA. ACE is available for use at no cost to the user. Free to access training is available, for example: https://www.mvls.gla.ac.uk/aceiiitrainer/register.aspx, but no particular training program is mandated by the test developers.
Rationale

**PICO question.** In patients with stroke (acute or post-acute), what is the accuracy of the Oxford Cognitive Screen (OCS) for contemporaneous diagnosis of dementia?

**Analysis of the current evidence**

In this PICO question we describe the accuracy of the Oxford Cognitive Screen (OCS) when used in the stroke context. The synthesis of test accuracy data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 7.

The Oxford Cognitive Screen (OCS) has been specifically developed to screen for domain-specific cognitive impairments after stroke. The OCS consists of 10 subtests that screen for impairments in five domains: language, attention, memory, praxis and numeric cognition. As the primary aim of the OCS is to detect domain-specific post-stroke impairments and not dementia, the OCS has been validated for this specific purpose.

We did not identify any studies that were aligned with our test accuracy paradigm of comparing OCS to a reference standard diagnostic formulation based on clinical assessment and/or detailed neuropsychological battery. The lack of published data may reflect the rationale that motivated development of the OCS, to move away from dichotomous assessments of impaired/non-impaired and offer clinicians a domain-by-domain summary of the presence and severity of cognitive impairments.

**Additional information**

We identified three studies that investigated the sensitivity and specificity of the OCS subtests relative to single-test reference standards for domain-specific impairment.\(^\text{[100][101][102]}\) In addition, we identified two studies investigated the ability of the OCS to discriminate stroke patients from healthy controls.\(^\text{[103][104]}\) All these data suggest that OCS can offer valid domain-specific assessment. However, while these methods of validation are appropriate, they do not answer our question of interest around test accuracy for cognitive syndromes. In particular, the accuracy of the reference standards used in these studies are debatable and discrimination of stroke survivors and healthy controls is not necessarily a good proxy for discriminating presence and absence of domain-specific cognitive impairment.

The OCS was designed to be inclusive for stroke patients. Multiple choice options are provided so that patients with expressive language difficulties can provide responses whenever possible. Executive function is evaluated with a trail making test that does not require intact alphanumeric knowledge. In addition, stimuli are presented centrally in the visual field as much as possible so
that patients with visuospatial difficulties can complete the test. Two studies have suggested that this inclusive design translates into better completion rates relative to the MoCA and MMSE.\textsuperscript{101,105} For example, in an Italian study of sequential admissions to stroke rehabilitation, OCS could not be fully completed in three of 325 patients, while MMSE was not possible in six.\textsuperscript{[101]} It should be noted that compared to the other tests considered (MoCA, MMSE, ACE) the studies describing properties of OCS are less biased by exclusion of stroke survivors with deficits that may interfere with testing. The OCS is available free of charge for all clinical use and publicly funded research. Online, free to access training in administration is available (https://www.ocs-test.org/how-to/).

### Consensus recommendation

The Oxford Cognitive Screen (OCS) offers advantages over other screening tools in terms of ease of completion and feasibility for stroke survivors with physical, language or visuospatial impairments.

Test accuracy studies of the OCS as a screen for post stroke dementia are required.

Those utilising the OCS should be trained in its administration.

Further comprehensive cognitive assessment is recommended in the event of a positive OCS and findings should be shared with the stroke care team.

### 8.11 Accuracy of remote assessment for contemporaneous diagnosis of dementia

### Weak recommendation

We suggest that in post-acute stroke settings, telephone-based screening of cognition can be considered. Telephone-based cognitive screening is not a substitute for comprehensive clinical assessment.

At conventional thresholds for test positivity, telephone-based screening will detect most people with important cognitive issues but at the cost of substantial false positives.

Test properties are sensitive to the threshold used to define test positivity, but there were insufficient data to make recommendations around the optimal cut-off for use in stroke.

**Quality of evidence:** Very Low ⊕

### Rationale

**PICO question.** In patients with stroke (acute or post-acute), what is the accuracy of remote assessment for contemporaneous diagnosis of dementia?

**Analysis of the current evidence**

In this PICO question we describe the accuracy of remote (not in person) cognitive assessment when used in the stroke context. Remote assessment could include telephone, video-based, or real time online assessment. We did not include postal questionnaires in the remit. The synthesis of test accuracy data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 7. We used the search strategy and synthesis of a recent review on the topic of telephone cognitive screening and extracted the papers specific to stroke.\textsuperscript{[106]}

Various cognitive screening tools have been described that can be used over the telephone or video conferencing platforms. We found four papers describing the accuracy of three different telephone-based tests in a stroke population.\textsuperscript{[87],[107],[108],[109]} We found no suitable papers describing video-based cognitive assessment for diagnosis of dementia following stroke.

In general, the papers had low risk of bias, but the varying proportions with dementia suggest that not all the populations studied are applicable to real world stroke practice.

We did not perform meta-analysis to give a summary estimate of test accuracy, due to the small number of studies and heterogeneity in the tests. Importantly, even when tests are described by the same name, they may have differing content. This is not unique to telephone assessment; for example, tests described as ‘short-form MoCA’ differ in the component items across the
Pendlebury et al. described the performance of three telephone screening tools – the Telephone Interview for Cognitive Status (TICS), the telephone-based Montreal Cognitive Assessment (t-MoCA) and a shortened version of the t-MoCA. Across 68 stroke survivors. There was a pattern of high sensitivity for detection of multi-domain cognitive problems, but lower specificity. Zietemann et al. described the performance of the TICS and t-MoCA in 105 participants of the DEDEMAS (Determinants of dementia after stroke) cohort. Both tests had reasonable sensitivity, but the t-MoCA had better specificity. Wong et al. assessed the short form t-MoCA on 104 participants of the STRIDE (stroke Registry Investigating Cognitive Decline) cohort. Desmond et al. assessed the TICS in 72 stroke survivors. In both studies there was reasonable accuracy with sensitivity better than specificity.

Our summary analyses (Table 7) suggest a common pattern of test properties for the telephone-based screening tools when used in stroke. Sensitivity tends to be high, with lower specificity and no clearly superior test. This implies that telephone assessment using these tools will detect most stroke survivors with dementia but at the cost of false positive screening tests. The relative risks and benefits of false positive and false negative diagnoses need to be considered for the person being assessed. Patients with a false positive test may require further, more detailed cognitive assessment. Patients with a false negative diagnosis may miss early intervention, but at present there is no proven intervention. For initial screening or triage, these properties are acceptable, but the telephone assessment is not a substitute for clinical diagnostic assessment.

Additional information

With the social distancing and other restrictions imposed by the Covid-19 viral pandemic, remote assessment of stroke survivors is increasingly used in research and in clinical practice. While the literature on stroke-specific remote cognitive assessment is limited, there is a more robust evidence base for telephone assessment of general and older adult populations. A recent review found 34 papers describing 15 different telephone-based cognitive assessments. TICS was the most studied assessment tool and properties in older adults were similar to those seen in stroke, with high sensitivity and lower specificity. However, properties could be altered by changing the threshold that defines a ‘positive’ test. This review identified limitations of telephone assessment that are relevant to stroke populations. Telephone testing makes assessment of visual-spatial function more difficult than in-person, pencil and paper testing. In addition, the feasibility of telephone testing may be reduced when used with people who have hearing impairment.

There is less supporting literature around video-based cognitive assessment. A recent review found 12 studies that included mixed populations and compared video to standard in-person assessment. The review authors reported that performance on certain tests was different when using a video-based platform, although differences were modest and may not have clinical importance. They concluded that best practice guidance is needed for video-based cognitive screening. A study of stroke survivors comparing in-person and video-based MoCA performance reached similar conclusions.

**Consensus recommendation**

There are inherent limitations to telephone based cognitive screening, but telephone screening can be useful in situations where in-person assessment is not practical.

Video call based cognitive screening shows promise in stroke, but further studies and best practice guidance around application and interpretation of results is needed.

Consideration should be given to the development and validation of specific telephone or video call cognitive screening tools or protocols.

Those utilising remote cognitive screening tests should be trained in their administration.

Further comprehensive cognitive assessment is recommended in the event of a positive screening test result and findings should be shared with the stroke care team.

8.12 Cholinesterase inhibitors for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden
Rationale

**PICO question:** In people with post-stroke cognitive impairments, do cholinesterase inhibitors, compared to placebo, delay cognitive decline or progression to dementia; improve behavioural and psychological symptoms, decrease caregiver burden and/or cause adverse effects?

**Analysis of the current evidence**

In this section we consider treatments for stroke survivors with an established cognitive syndrome, either post-stroke cognitive impairment or dementia. Currently, there is no pharmacological treatment approved for post-stroke cognitive impairment. Efficacy of cholinesterase inhibitors in mild to moderate Alzheimer's disease is established, and donepezil, galantamine, and rivastigmine are approved for symptomatic treatment in Alzheimer's and other dementia types.[113][114][115] Here, we aimed to evaluate the potential utility of cholinesterase inhibitors in post-stroke cognitive impairment. We pre-specified outcomes of interest relating to cognitive decline, behavioural and psychological symptoms (BPSD), caregiver burden, adverse effects (AE).

We found several trials of cholinesterase inhibitor in vascular dementia but only one trial with a specific focus on post-stroke cognitive impairment. Narasimhalu et al.[116] described the effect of oral rivastigmine titrated up to 9 mg/day (4.5mg oral twice daily) in 50 participants with a history of recent stroke (25 patients in each arm) who had evidence of post-stroke cognitive impairment without criteria of dementia at randomization. There was no benefit of rivastigmine across the primary outcomes (executive functions). There were no differences concerning global cognitive evaluation, function and activities of daily living, behavioural and psychological symptoms (Table 8). There were no relevant adverse events reported. Impact on caregiver outcomes was not studied. The study was low risk of bias across all domains but with a single, under-powered study there were serious concerns over precision and publication bias.

**Additional information**

We found seven randomized trials describing the use of cholinesterase inhibitors in vascular dementia (donepezil, three trials n=2193[117][118][119]; rivastigmine, two trials n=750 [120][121] and galantamine, two trials n=1380[122][123]). While most of the trials assessed adverse events and cognitive outcomes, very few evaluated behavioural effects, and none assessed the impact on caregiver related outcomes. Some of those studies included patients with previous stroke,[118][119][120][123] so these data are relevant to our PICO question, but subgroup analysis restricted to participants with stroke was not possible. Precise subtyping of dementia is difficult and in older adults mixed pathologies are common, so the interpretation of data in a ‘vascular’ dementia review needs to be mindful of this. One open trial with 73 patients studied caregiver reported outcomes in multi-infarct dementia, but the outcomes of interest for our analysis were not evaluated.[124] A recent Cochrane review performed network meta-analysis of trials using cholinesterase inhibitors (including the Narasimhalu trial of a post-stroke population) and found varying quality evidence that donepezil and galantamine may improve cognition compared to placebo, but the effect may not be sufficiently large to be clinically important.[125] There was low certainty evidence that rivastigmine had no significant effect on cognition. There was moderate certainty evidence that donepezil at higher dose and galantamine may increase adverse events but not serious adverse events.

We found one trial of donepezil used in the monogenic condition Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) (168 participants, a proportion had previous stroke or transient ischaemic attack).[126] This condition offers a model of pure vascular dementia, due to cerebral small vessel disease, in a younger population unlikely to have co-existent age-related Alzheimer's pathology. There was no significant difference in the primary cognitive endpoint of vascular AD assessment scale cognitive subscale (V-ADAS-cog) at 18 weeks. There were small but significant improvements in executive function, but these had no impact on instrumental activities of daily living. This suggested that even though there may be a small biological effect, treatment had no clinically meaningful effect.

Although with a lower degree of evidence compared to Alzheimer's disease (based on a single study or in post-hoc analyses of Alzheimer's Disease or vascular dementia subgroups trials), utility of cholinesterase inhibitors has been reported for mixed dementia (Alzheimer's disease plus vascular dementia).[127]
8.13 Memantine for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden

In people living with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of memantine for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden.

Quality of evidence: Very Low ⊕

Rationale

**PICO question:** In people with post-stroke cognitive impairments, does memantine compared to placebo, delay cognitive decline or progression to dementia, improve behavioural and psychological symptoms, decrease caregiver burden and/or cause adverse effects?

**Analysis of the current evidence**

Memantine, a glutamate NMDA receptor antagonist is approved for use as a symptomatic treatment in moderate to severe dementia due to Alzheimer’s disease, and can be used alone or added to cholinesterase inhibitors.[128] We were interested in the potential utility of memantine in post-stroke cognitive impairment and we specified outcomes relating to cognitive decline, BPSD, caregiver burden and AE.

We found no study specifically describing the effect of memantine in post-stroke cognitive impairment without dementia.

**Additional information**

We found three studies of memantine in vascular dementia (n=928). Two studies did not specifically consider post-stroke populations,[129][130] and the third evaluated only language deficits.[131] A recent Cochrane review found a probable small clinical benefit among patients with vascular dementia,[128] it was not possible to assess the subgroup of participants with previous stroke. The review reported moderate to low quality evidence that memantine may improve cognition and behaviour, but the differences were unlikely to be clinically important. There was high quality evidence of an increase in total adverse events, but not serious adverse events, with memantine. Another meta-analysis considering, both memantine and cholinesterase inhibitors, focussed on cognitive outcomes specifically the mini-mental state examination (MMSE) and described low potential efficacy of memantine when considering vascular dementia as subgroup.[132]
8.14 Actovegin or cerebrolysin for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden

Actovegin

Rationale

**PICO question:** In people with post-stroke cognitive impairments, do the nootropics *actovegin* or *cerebrolysin*, compared to placebo improve cognitive decline, improve behavioural and psychological symptoms, reduce caregiver burden and/or increase adverse events.

**Analysis of the current evidence**

Actovegin and cerebrolysin are animal-derived nootropics, that may have potential efficacy in the treatment of neurodegenerative disease.[133] These agents are used in many countries for conditions such as dementia, stroke and traumatic brain injury, but unlike other drugs considered in this guideline (cholinesterase inhibitors, memantine) the nootropics do not have international approval for use in dementia. The mechanisms of action of the nootropics are not clear, but putative vascular effects have been described, so there is an assumption of a potential efficacy in vascular cognitive syndromes.[134] We were interested in the potential effect of these agents in post-stroke cognitive impairment and specified outcomes relating to cognitive decline, BPSD, caregiver burden and AE.

We found one double blinded RCT of actovegin used in a post-stroke population exploring cognitive outcomes.[135] The ARTEMIDA trial randomised 503 participants within seven days after ischaemic stroke. The intervention consisted of daily infusions of actovegin for 20 days followed by oral actovegin for six months. Primary outcome was defined as a change in cognitive function measured through ADAS-Cog. A beneficial effect of actovegin compared to placebo was reported, but the effect size described may be less than the minimal clinically important difference. Other related outcomes (change in a global cognitive test, rates of incident dementia) did not show significant between group differences. The intervention involved daily intravenous infusions for up to 20 days, with associated cost and burden. More participants taking actovegin had to discontinue study drug (4.7% versus 8.4%). The most frequent adverse event was recurrent ischaemic stroke and there were higher absolute numbers of recurrent stroke events in those taking actovegin (14 versus 7 [absolute numbers]). While these differences were not ‘significant’ we felt there was sufficient signal of concern for these data to inform our Expert Consensus statement. The trial was low risk of bias, but as a single study we noted imprecision, inconsistency across the included cognitive outcomes and potential for publication bias. In formulating our recommendation, we considered efficacy, potential for harm and costs (Table 9).

We found reviews of trials of cerebrolysin when used in stroke and vascular dementia populations, but no trials with an exclusive focus on post-stroke cognitive impairment.[136][137]

**Additional information**

We found six trials (n=597 participants) describing the use of cerebrolysin in vascular dementia. These data were summarised in
Cerebrolysin

In patients with post-stroke cognitive impairment there is continued uncertainty over the benefits and risks of cerebrolysin.

Quality of evidence: Very Low ⊕

Rationale

**PICO question:** In people with post-stroke cognitive impairments, do the nootropics actovegin or cerebrolysin, compared to placebo improve cognitive decline, improve behavioural and psychological symptoms, reduce caregiver burden and/or increase adverse events.

**Analysis of the current evidence**

Actovegin and cerebrolysin are animal-derived nootropics, that may have potential efficacy in the treatment of neurodegenerative disease.[133] These agents are used in many countries for conditions such as dementia, stroke and traumatic brain injury, but unlike other drugs considered in this guideline (cholinesterase inhibitors, memantine) the nootropics do not have international approval for use in dementia. The mechanisms of action of the nootropics are not clear, but putative vascular effects have been described, so there is an assumption of a potential efficacy in vascular cognitive syndromes.[134] We were interested in the potential effect of these agents in post-stroke cognitive impairment and specified outcomes relating to cognitive decline, BPSD, caregiver burden and AE.

We found one double blinded RCT of actovegin used in a post-stroke population exploring cognitive outcomes.[135] The ARTEMIDA trial randomised 503 participants within seven days after ischaemic stroke. The intervention consisted of daily infusions of actovegin for 20 days followed by oral actovegin for six months. Primary outcome was defined as a change in cognitive function measured through ADAS-Cog. A beneficial effect of actovegin compared to placebo was reported, but the effect size described may be less than the minimal clinically important difference. Other related outcomes (change in a global cognitive test, rates of incident dementia) did not show significant between group differences. The intervention involved daily intravenous infusions for up to 20 days, with associated cost and burden. More participants taking actovegin had to discontinue study drug (4.7% versus 8.4%). The most frequent adverse event was recurrent ischaemic stroke and there were higher absolute numbers of recurrent stroke events in those taking actovegin (14 versus 7 [absolute numbers]). While these differences were not 'significant' we felt there was sufficient signal of concern for these data to inform our Expert Consensus statement. The trial was low risk of bias, but as a single study we noted imprecision, inconsistency across the included cognitive outcomes and potential for publication bias. In formulating our recommendation, we considered efficacy, potential for harm and costs (Table 9).

We found reviews of trials of cerebrolysin when used in stroke and vascular dementia populations, but no trials with an exclusive focus on post-stroke cognitive impairment.[136][137]

**Additional information**

We found six trials (n=597 participants) describing the use of cerebrolysin in vascular dementia. These data were summarised in a recent Cochrane review.[136] This review included people living with post-stroke dementia, and so these data are relevant to our PICO question. The review found very low-quality evidence that cerebrolysin may improve cognition compared to placebo, but the effect may not be sufficiently large to be clinically important. There was very low-quality evidence that rates of serious adverse events were not different between cerebrolysin and placebo. Factors such as economic and opportunity cost (cerebrolysin needs to be administered as a frequent intravenous infusion) and longer-term effects (most studies followed...
participants for weeks to months only) were not considered in the Cochrane review but are important for decision making.

We found seven trials (n=1601 participants) describing cerebrolysin in acute stroke and these were described in a recent review.[137] The review found moderate quality evidence that cerebrolysin had no effect on mortality, but the intervention was associated with possible increased adverse event rates. We are aware of trials of cerebrolysin as an adjunct to motor rehabilitation following stroke, but we considered these out of the scope of this review.[138]

We found a recent review describing Actovegin in acute stroke, but with exception to the trial described above, the remaining information was mainly derived from laboratory studies and no included papers considered cognitive impairment after stroke.[139]

**Consensus recommendation**

The available evidence suggests that any cognitive benefits of actovegin and cerebrolysin are likely to be modest and there is risk of serious adverse events with treatment. Considering the balance of risks and harms, we suggest against using these agents for post stroke cognitive impairment.

Replication of the single available trial for Actovegin is needed.

Any further trials of actovegin and cerebrolysin should be adequately powered, have longer term follow-up and consider patient reported outcomes and health economic measures.

**8.15 Cognitive rehabilitation for cognition, behavioural and psychological symptoms, activities of daily living and caregiver burden**

Due to a lack of methodologically robust trials, for most cognitive rehabilitation interventions, there is continued uncertainty on the benefits and limitations associated with these interventions for stroke survivors.

Quality of evidence: Very low ◊

**Rationale**

**PICO question:** In people with post-stroke cognitive impairments, does cognitive rehabilitation (cognitive skill training or compensation strategies) compared to no rehabilitation, delay cognitive decline or progression to dementia, improve behavioural and psychological symptoms, improve performance in activities of daily living or decrease caregiver burden?

**Analysis of the current evidence**

For the purpose of the present guidelines, we define cognitive rehabilitation as an individualised, structured set of therapeutic activities designed to restore domain-specific cognitive impairments (e.g. attention, visuospatial processing, memory, executive functions) or global cognitive impairment, or overcome these cognitive impairments by means of compensation (e.g. adaptive strategies, assistive devices).[140] Generally, cognitive rehabilitation includes a combination of restorative and compensatory approaches. The ultimate goal of cognitive rehabilitation is minimizing the impact of cognitive impairments on personally relevant aspects of everyday functioning for both the affected individuals and their families.

Given the potential variation in the activities that could be considered as relevant to the cognitive rehabilitation rubric, we pre-specified a list of non-pharmacological interventions that could be considered in the management of post-stroke cognitive impairments but were not considered in this cognitive rehabilitation review. This is an approach that has been used in previous systematic reviews of cognitive rehabilitation.[141] We considered that interventions exclusively targeting communication, reading, writing and calculation disorders fall outside the scope of the present guidelines, and they are not considered here. Furthermore, we decided to exclude disease self-management/coping interventions, cognitive-motor dual task training, physical training, community reintegration, vocational rehabilitation, patient and caregiver education, neurosensory stimulation (i.e. Snoezelen therapy), nutritional supplements, music-based therapy/instrument playing, art therapy, mindfulness-based interventions, yoga, qigong, acupuncture, non-invasive brain stimulation and cognitive behavioural therapy delivered in isolation or as part of multimodal interventions. We acknowledge that some or all of these interventions might – directly or indirectly – benefit cognitive functioning and therefore could be considered in future versions of these guidelines.

For this PICO, we pre-specified that we would only include randomised controlled trials (RCTs) as observational data in the field.
are prone to many biases. We also pre-specified that trials would require a minimum of 50 stroke survivors per arm, because we felt as a writing group that smaller studies should be considered proof of concept and their inclusion would make recommendation more prone to publication bias.

We identified a substantial number of controlled clinical trials on cognitive rehabilitation. However, only one trial fulfilled our eligibility criteria. Donkervoort et al.[142] investigated the efficacy of strategy training for improving functioning in activities of daily living (ADL, primary outcome) and reducing cognitive impairment following left hemisphere stroke with apraxia. One hundred and thirteen subacute stroke survivors (mean time since stroke: 100 days) were randomized to an intervention group (n=56) receiving 15 hours (SD:7.7 hours) of strategy training integrated into usual occupational therapy and a control group (n=57) receiving 19 hours (SD:15.0 hours) usual occupational therapy alone over an eight-week period (Table 10). The intervention used compensatory strategies that can be internal (e.g. self-verbalization) or external (e.g. using pictures of the correct task sequence). Outcomes included observation in four tasks undertaken at baseline, after the 8-week intervention period and at 5 months after baseline. The trial had several methodological limitations including, selected sample, ceiling effect of the ADL observations and 25% drop-out in each trial arm. Strategy training did not influence the apraxic impairment. Regarding ADL functioning, the trial suggested a potential improvement of 0.13 (90%CI:0.00-0.25) in favour of strategy training post-intervention, corresponding to a small-to-medium effect size. This beneficial effect was not maintained at follow-up.

**Additional information**

Currently, there is an urgent need for methodologically robust trials to support recommendations for clinical practice in cognitive rehabilitation. Despite an increased focus on the importance of cognitive rehabilitation in recent decades, the evidence base is generally characterized by trials with limited methodological quality, e.g. inadequate sample size to detect clinically important intervention effects, study designs without control groups and lacking consensus on optimal outcome measures.[143][144]

There is an emerging evidence for beneficial effect of cognitive rehabilitation based on re-learning of compensatory strategies, particularly in the context of individually relevant functional tasks. Although it is established that learning processes require long-term and intensive efforts, existing trials have provided only short periods of cognitive therapy, possibly delivered at insufficient dose to produce a meaningful benefit. Furthermore, trials often lack long-term follow-up and fail to demonstrate evidence of long-lasting intervention effect, and transfer effects to untrained cognitive domains and/or functional tasks. Evaluation of strategies to maintain (e.g. booster sessions) and transfer effects are consequently warranted. Little is known about the spontaneous recovery of cognitive impairments over time, this representing a considerable challenge when assessing the true effect of the interventions.

Our choice of outcomes followed the standardised GRADE process and we reached consensus on the critical outcomes. Choice of outcomes was, in part, to maintain consistency with the other PICO questions in this guideline. Many of the studies returned on our literature search were designed to understand if the intervention improves everyday cognitive function. This is clearly an important outcome and should be considered in future iterations of this guideline.

A final issue we encountered when reviewing the literature is that most trials include populations with mixed diagnoses of stroke and traumatic brain injury. Currently, there is insufficient knowledge on how people recover with similar cognitive impairments, but different aetiology and so we made the decision to exclude trials with mixed populations from the present guidelines. We appreciate that there is debate on this issue, some argue that given the difficulty in recruiting to cognitive rehabilitation trials future trials may need to be pragmatic and include various brain injuries and adjust for age, psychological and medical comorbidity; while others argue that we should strive for purity in case-mix.

**Consensus recommendation**

Although many of the available studies did not meet our inclusion criteria for this PICO, there is emerging evidence that cognitive rehabilitation, particularly compensatory strategies in the context of individually relevant functional tasks, may be beneficial for people with post-stroke cognitive impairments.

Methodologically robust trials to support definitive recommendations for clinical practice are needed.

**8.16 Multi-item prognostic tools for the prediction of future cognitive decline or dementia**
There is continued uncertainty over the advantages and disadvantages of using multi-item prognostic tools to predict cognitive outcomes following stroke.

Quality of evidence: Very Low 🌌

Rationale

**PICO question.** In people with a history of stroke, do multi-item prognostic tools performed soon after stroke, predict future cognitive decline or dementia.

**Analysis of the current evidence**

In this PICO, we consider multi-item prognostic or prediction tools. i.e. assessments that apply scores to a combination of demographic, clinical, radiological or other data to determine the likelihood of a potential outcome, in this case cognitive decline or dementia. We focussed our attention on tools applied in the acute stroke period (first days to weeks). Prognostic tools have been developed and validated for many aspects of stroke care\[145\], for example risk of stroke in a person with atrial fibrillation is assessed using the CHADS\textsubscript{2}V\textsubscript{a}SC tool\[146\]; risk of poor outcome can be assessed with the ASTRAL and other tools.\[147\] A similar tool for predicting cognitive outcomes could be useful for ongoing management and discussions with patients and families. However, if such tools are inaccurate in their predictions this could lead to inappropriate treatment decisions or erroneous and potentially harmful discussions regarding future health with the patient and family.

The methods underpinning prognosis evidence synthesis differ in some regards from the standard analysis of trial data. In particular, the application of GRADE to prognosis tools is not as well developed as it is for synthesis of intervention studies. In our GRADE assessment we used the approach of Cochrane prognostic reviews\[148\] and considered risk of bias and applicability using the Prediction model Risk Of Bias Assessment Tool (PROBAST) tool\[149\], we considered internal consistency through visual inspection of study level estimates and considered the precision of the summary estimate. More detailed descriptions and examples of prognosis evidence synthesis and reporting are available from Cochrane and others. While we refer to these questions using the PICO terminology, our questions are considering prognostic utility rather than comparative efficacy of interventions, so in formulating these questions our concepts of interest were the population, prognostic factor, outcome and timing of outcome.

Our literature review was based on a recent systematic review\[150\] and found seven prognostic tools\[151\]-\[152\],\[153\]-\[154\],\[155\]-\[156\],\[157\], that had been applied in an acute stroke population and were designed to predict a variety of future cognitive outcomes. Eligible studies were from Europe and Asia and included a variety of stroke types. Five studies assessed for cognitive decline (change in a cognitive score) and two studies assessed for a future diagnosis of dementia (clinical diagnosis). Studies were generally of modest size (range 92 to 283 participants). Variables included in the prognostic tools were items relating to demographics (age, education); stroke severity (NIHSS, GCS); imaging features (atrophy, white matter disease) and scores on cognitive screening tests performed in the acute period.

We assessed methodological quality of the included studies using the PROBAST tool and judged all the included studies at risk of bias (Supplementary Materials). Common limitations of the studies were issues of sample size, handling missing data and lack of external validation. Our intention was to limit our recommendations to those studies that assessed for cognitive outcomes later than one year after index stroke. However, none of the included studies had this length of follow-up and most assessed outcomes at three-six months. We included this shorter follow-up for our PICO recommendation but recognise that post-stroke cognition is dynamic and may still be evolving at three and even six months post-event. Most included studies presented prognostic utility as an area under an ROC curve. There was a range of scores and most studies had values that would be considered reasonable (Table 11). However, given the low quality of evidence for the tools, we could not recommend one over another.

**Additional information**

In addition to the studies looking at post-stroke cognitive change, we also found four papers describing prediction tools for post-stroke delirium.\[158\]-\[159\],\[160\],\[161\] These tools considered similar factors to the tools looking at cognitive decline and dementia. Common factors included demographics (age), stroke severity (NIHSS), stroke type (ischaemia or haemorrhage) and laboratory results (inflammatory markers). Similar to the tools for predicting future cognitive outcomes, and indeed similar to much of the stroke prognosis literature\[162\], the delirium prediction tools had methodological issues around sample size, missing data and lack of external validation.

Many prediction tools have been developed for all cause or Alzheimer’s dementia. A recent review identified over 70 such tools.\[163\] Here again most of the studies have methodological limitations that preclude recommending one tool over any of the
others. However, the authors noted that design, conduct and interpretation of studies looking at dementia prediction tools was improving over time.

Studies to date have considered the prognostic accuracy of multi-item prediction tools. We found no trials that described whether the use of a cognitive outcomes prediction tool improved outcomes or changed care pathways.

8.17 Structural features on acute brain CT imaging for the prediction of future cognitive decline or dementia

In patients with acute stroke there is continued uncertainty regarding the value of acute CT-brain imaging findings for predicting cognitive outcomes more than one year after stroke.

Quality of evidence: Very Low ⋂

Rationale

PICO question: In people with a history of stroke, do structural features on acute brain CT imaging, predict (at least one year from index stroke event) future cognitive decline or dementia.

Analysis of the current evidence

In this PICO question we describe the accuracy of neuroimaging features seen on CT brain scans performed as part of acute stroke care. Although, increasingly sophisticated approaches to brain imaging are available, CT brain remains the most used imaging modality in International acute stroke care and so we felt that an assessment of cognitive prognosis was warranted. The synthesis of prognosis data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 16. In this analysis, we are describing prognosis in relation to a single prognostic factor (CT imaging finding), rather than a collection of different factors. Thus, for quality assessment we used the QUIPS tool (quality in prognostic factor studies).

Our literature review found 13 studies examining associations between CT-brain imaging variables and post-stroke dementia or post stroke cognitive impairment (PSCI) ascertained at least 12 months after stroke (Table 12 and Supplementary Materials). Six studies reported on post-stroke dementia[167][168][169][170][171][172][173][174][175][176][177] and one study reported both[176]. All seven dementia studies excluded patients with prior dementia/cognitive impairment and three excluded patients with prior stroke. Five of seven PSCI studies excluded prior dementia/cognitive impairment and three excluded prior stroke. Reported associations were therefore largely with new post-stroke dementia/PSCI rather than pre-existing dementia. Studies were generally of modest size (range 47 to 445 participants). CT variables examined included atrophy (presence and or severity of generalized atrophy, medial temporal lobe atrophy), white matter hyperintensity (leukoaraiosis) (WMH, presence and or severity), silent brain infarcts (SBI) and acute stroke lesion characteristics although not all features were reported in every study. There was considerable heterogeneity in the way variables were measured.

We assessed methodological quality using the QUIPS tool[164] and judged all the included studies at risk of bias (Supplementary Materials). Common limitations were small sample sizes, attrition and handling of missing data. In addition, few studies adjusted associations for important covariates.

Given the small number of studies per imaging variable and the heterogeneity between studies, we did not create summary estimates, full details of the included papers and their study level results are in Supplementary Materials. Two studies reported
on presence vs absence of atrophy and dementia. One showed an association with dementia (OR=5.86, 95%CI=1.73-19.87)\textsuperscript{175}, the other suggested a possible association, but with substantial uncertainty in the estimate (OR=7.7, 95%CI=0.9-65.2)\textsuperscript{176}.

Three studies examined atrophy and PSCI, of which only one reported a positive association with PSCI (p<0.001, no size of effect)\textsuperscript{166}, one approached a positive association (OR=2.2, 95%CI:0.9-5.1)\textsuperscript{176} and one found no association.\textsuperscript{177} Three studies examined severity of atrophy\textsuperscript{170}\textsuperscript{172}\textsuperscript{175}; only one of which reported significant associations between post stroke dementia and severe generalized atrophy (RR=2.19, 95%CI=1.5-3.17) and between post stroke dementia and medial temporal lobe atrophy (RR=2.3, 95%CI=1.1-4.7)\textsuperscript{170}.

All studies examining presence vs absence of WMH reported positive associations with dementia\textsuperscript{174}\textsuperscript{175}\textsuperscript{176} e.g. OR=3.9, 95%CI=1.2-12.0 (unadjusted),\textsuperscript{175} but relationships between WMH and PSCI were less certain. Severity of WMH was associated with dementia in three\textsuperscript{167}\textsuperscript{175}\textsuperscript{170} of five studies\textsuperscript{172}\textsuperscript{177} (e.g. RR=2.09, 95%CI:1.05-4.13). Two\textsuperscript{170}\textsuperscript{176} of three studies\textsuperscript{168} found associations between SBI and post-stroke dementia: OR=5.6, 95%CI:1.4-22.5 and RR=2.09, 95%CI:1.05-4.13. Acute stroke features were too heterogeneous to draw conclusions regarding their associations with post stroke cognitive outcomes.

**Additional information**

There are many studies of CT-brain imaging in relation to all-cause dementia and specifically for Alzheimer's dementia.\textsuperscript{178} These studies show associations between WMH and cognitive function (and also gait and balance and functional disability) including prediction of cognitive decline and dementia. Similar associations have been demonstrated between generalized cerebral atrophy\textsuperscript{179} and temporal lobe atrophy\textsuperscript{180} and Alzheimer's dementia.

It would seem intuitive that the presence of findings such as atrophy and WMH on CT brain imaging performed for acute stroke would indicate a prevalent neurodegenerative process and so would be associated with future cognitive outcomes. However, in our PICO analysis described above we found only a limited published literature. Thus, the prognostic utility of these CT imaging biomarkers, in particular their utility over and above the basic clinical and demographic factors already known to be associated with future dementia, remains to be described with adequate certainty and precision.

The clinical-radiological correlations described in the stroke and general dementia themed papers are not perfect. In older adults in particular, the relationship between neuroimaging features and the clinical phenotype can be weak.\textsuperscript{181} It seems possible that single factors alone may never be sufficiently predictive to alter clinical pathways.

In this review, we have considered only the prognostic properties of the imaging features. A more complex but more clinically relevant question is whether knowledge of the likely cognitive prognosis makes a difference to patient outcomes. With no proven acute interventions to arrest or delay potential post stroke cognitive consequences, it could be argued there is no value in acute prognostication. To study this question would require a different study paradigm where patients or centres are randomised to using a prediction tool and patient pathways and outcomes are described. We found no studies that used this approach.

### Consensus recommendation

As CT is the most widely available and commonly used imaging modality in acute stroke, a better understanding of the prognostic value of the imaging findings for future cognitive prognosis would be useful.

Further studies of the predictive value of CT-based imaging variables should use standardized measurements and validated tools.

Consideration needs to be given to the population included, with preferably unselected samples and low rates of attrition from cognitive follow-up.

Results of these studies need appropriate adjustments to distinguish the added prognostic value of CT imaging features over standard clinical factors such as age, sex and stroke severity.

### 8.18 Structural features on acute brain MR imaging for the prediction of future cognitive decline or dementia
White matter hyperintensities

**Weak recommendation**

We suggest that in patients with acute stroke, the presence of substantial white matter hyperintensities of presumed vascular origin on acute MRI brain may help predict cognitive outcomes more than one year after stroke.

**Quality of evidence:** Moderate ⊕ ⊕ ⊕

**Rationale**

**PICO question:** In people with a history of stroke, do structural features on acute brain MR imaging, predict (at least one year from index stroke event) future cognitive decline or dementia.

**Analysis of the current evidence**

In this PICO question, we describe the accuracy of neuroimaging features seen on standard MRI brain scans performed as part of acute stroke care. The synthesis of prognosis data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 16 and 17. Brain imaging is invariably performed in acute stroke for diagnostic purposes and to guide treatment decisions. Although CT is standard practice in acute stroke, MRI is used frequently, especially in regional centres in the developed world, so a better understanding of the prognostic value of routinely acquired MR-brain imaging findings for future cognitive prognosis is required.

We found ten relevant studies of consecutive stroke patients examining associations between MR-brain imaging variables and cognition. Nine [182,183,184,185,186,187,188,189] described PSCI outcomes and were included in our GRADE table assessment (Table 13), a single study described post-stroke dementia defined using NIA-AA criteria [175] (Supplementary Materials). Studies used a variety of methods to define PSCI (multidomain cognitive screening tools and differing neuropsychological batteries). Two studies did not exclude patients with prior dementia/cognitive impairment [182,187] and five excluded patients with prior stroke [182,185,187,188,190]. Reported associations were therefore largely but not exclusively with new post-stroke PSCI rather than pre-existing dementia/PSCI. Studies were generally of small or modest size (range 55 to 451 participants). MR variables examined included white matter hyperintensities of presumed vascular origin (WMH), global atrophy, stroke lesion volume, cerebral microbleeds, perivascular spaces, stroke lesion related factors including stroke location and an aggregate small vessel disease score (combining different features of SVD). Not all features were reported in every study. There was considerable heterogeneity in the way variables were measured.

Common study limitations were small sample sizes, attrition, handling of missing data, lack of standardization of measures and adjustment for important covariates. In addition, outcome measures for PSCI were heterogeneous and the predominant use of cognitive screening tools may have missed subtle yet important changes.

Given the small number of studies per imaging variable and the heterogeneity between studies, we did not create summary estimates. Full details of the included papers and their study level results are in Supplementary Materials.

The paper that reported post-stroke dementia outcomes [175] included 218 participants and described positive association with WMH (Fazekas score), HR=1.80, 95% CI: 1.17-2.75 (p=0.007, adjusted for age) and positive association with cortical atrophy score, HR=2.02, 95% CI: 1.28-3.19 (p=0.002, adjusted for age).

For PSCI, most evidence was available for WMH although again there was heterogeneity in measurement method as well as outcome assessment. Overall, six [184,185,186,187] of eight studies examining WMH reported positive association with PSCI and this was robust to adjustment at least for demographic factors (eg OR=1.58 (95% CI: 1.15-2.44), adjusted, total Fazekas score; OR=1.52 (95% CI: 1.01-2.29), Fazekas 0-3, unadjusted). Only two studies examined atrophy (global) [186,189], one of which showed associations in unadjusted but not adjusted analyses [189]. Lesion volume findings were conflicting with associations reported with a number of cognitive domains including spatial memory, recall but not global cognitive impairment by the MMSE. Acute stroke features were variably examined and too heterogeneous to draw conclusions.

Many of the papers described various small vessel disease features including cerebral microbleeds [183,184,185,186] and perivascular spaces [185,186,187]. Findings for cerebral microbleeds were conflicting and no associations were seen with perivascular spaces. Three studies examined a global small vessel disease score combining different imaging features of small vessel disease [185,186,187]. Two [185,186] of three found associations in adjusted analyses and the use of combination measures is promising but at present there are too few data to draw conclusions about their clinical utility in this context.

**Additional information**

There are many studies of MR-brain imaging in relation to all-cause dementia and specifically for Alzheimer’s dementia. These
studies show associations between WMH and cognitive function (and also gait and balance and functional disability) including prediction of cognitive decline and dementia. Similar associations have been demonstrated between generalized cerebral atrophy and all-cause dementia and between temporal lobe atrophy and Alzheimer's dementia, although specificity for Alzheimer's disease is not 100%.

The predictive value of baseline brain imaging findings for dementia at more than one year post stroke has also been examined in large cohorts in which brain imaging variables were obtained using either CT- or MRI (n= 919, Mok et al and n=2305 Pendlebury et al, [194][195] Both these studies, which excluded pre-stroke dementia, showed strong associations with WMH (MRI) and leukoaraiosis (CT) and late post-stroke dementia (OR=1·49 (95%CI:1·22–1·82) adjusted for age, sex, education, stroke severity, Pendlebury et al) and presence of ≥3 lacunes and confluent WMH (OR=2.6 (95%CI:1.3–4.9) adjusted age, sex, education, Mok et al).

We also reviewed the evidence for MR-brain imaging features based on non-structural MRI modalities to predict the cognitive outcomes after stroke: the most commonly used modalities were Diffusion Tensor Imaging (DTI), Diffusion Weighted Imaging (DWI) and functional MRI. The evidence was inconclusive as most studies used small sample sizes (n=1-148), combined with a maximal follow-up of 6 months, or focused exclusively on aphasia, which is less relevant to our PICO.

Acute MRI brain imaging findings

In patients with acute stroke there is continued uncertainty regarding the value of acute MRI brain imaging findings, other than white matter hyperintensities, to predict cognitive outcomes more than one year after stroke.

Quality of evidence: Very Low ⊕

Rationale

**PICO question:** In people with a history of stroke, do structural features on acute brain MR imaging, predict (at least one year from index stroke event) future cognitive decline or dementia.

**Analysis of the current evidence**

In this PICO question, we describe the accuracy of neuroimaging features seen on standard MRI brain scans performed as part of acute stroke care. The synthesis of prognosis data is different to that of the standard intervention review. A discussion of the methods that underpin our approach is provided in PICO 16 and 17. Brain imaging is invariably performed in acute stroke for diagnostic purposes and to guide treatment decisions. Although CT is standard practice in acute stroke, MRI is used frequently, especially in regional centres in the developed world, so a better understanding of the prognostic value of routinely acquired MR-brain imaging findings for future cognitive prognosis is required.

We found ten relevant studies of consecutive stroke patients examining associations between MR-brain imaging variables and cognition. Nine [182][183][184][185][186][187][188][189][190] described PSCI outcomes and were included in our GRADE table assessment (Table 13), a single study described post-stroke dementia defined using NIA-AA criteria [175] (Supplementary Materials). Studies used a variety of methods to define PSCI (multidomain cognitive screening tools and differing neuropsychological batteries). Two studies did not exclude patients with prior dementia/cognitive impairment and five excluded patients with prior stroke. Reported associations were therefore largely but not exclusively with new post-stroke PSCI rather than pre-existing dementia/PSCI. Studies were generally of small or modest size (range 55 to 451 participants). MR variables examined included white matter hyperintensities of presumed vascular origin (WMH), global atrophy, stroke lesion volume, cerebral microbleeds, perivascular spaces, stroke lesion related factors including stroke location and an aggregate small vessel disease score (combining different features of SVD). Not all features were reported in every study. There was considerable heterogeneity in the way variables were measured.

Common study limitations were small sample sizes, attrition, handling of missing data, lack of standardization of measures and adjustment for important covariates. In addition, outcome measures for PSCI were heterogeneous and the predominant use of cognitive screening tools may have missed subtle yet important changes.

Given the small number of studies per imaging variable and the heterogeneity between studies, we did not create summary estimates. Full details of the included papers and their study level results are in Supplementary Materials.

The paper that reported post-stroke dementia outcomes [175] included 218 participants and described positive association with WMH (Fazekas score), HR=1.80, 95%CI:1.17–2.75 (p=0.007, adjusted for age) and positive association with cortical atrophy score, HR=2.02, 95%CI:1.28–3.19 (p=0.002, adjusted for age).

For PSCI, most evidence was available for WMH although again there was heterogeneity in measurement method as well as...
outcome assessment. Overall, six studies examining WMH reported positive association with PSCI and this was robust to adjustment at least for demographic factors (eg OR=1.58 (95%CI:1.15-2.44), adjusted, total Fazekas score; OR=1.52 (95%CI:1.01-2.29), Fazekas 0-3, unadjusted). Only two studies examined atrophy (global), one of which showed associations in unadjusted but not adjusted analyses. Lesion volume findings were conflicting with associations reported with a number of cognitive domains including spatial memory, recall but not global cognitive impairment by the MMSE. Acute stroke features were variably examined and too heterogeneous to draw conclusions.

Many of the papers described various small vessel disease features including cerebral microbleeds and perivascular spaces. Findings for cerebral microbleeds were conflicting and no associations were seen with perivascular spaces. Three studies examined a global small vessel disease score combining different imaging features of small vessel disease. Two of three found associations in adjusted analyses and the use of combination measures is promising but at present there are too few data to draw conclusions about their clinical utility in this context.

Additional information

There are many studies of MR-brain imaging in relation to all-cause dementia and specifically for Alzheimer’s dementia. These studies show associations between WMH and cognitive function (and also gait and balance and functional disability) including prediction of cognitive decline and dementia. Similar associations have been demonstrated between generalized cerebral atrophy and all-cause dementia and between temporal lobe atrophy and Alzheimer’s dementia, although specificity for Alzheimer’s disease is not 100%.

The predictive value of baseline brain imaging findings for dementia at more than one year post stroke has also been examined in large cohorts in which brain imaging variables were obtained using either CT- or MRI (n= 919, Mok et al and n=2305 Pendlebury et al). Both these studies, which excluded pre-stroke dementia, showed strong associations with WMH (MRI) and leukoaraiosis (CT) and late post-stroke dementia (OR=1.49 (95%CI:1.22–1.82) adjusted for age, sex, education, stroke severity, Pendlebury et al) and presence of ≥3 lacunes and confluent WMH (OR=2.6 (95%CI:1.3–4.9) adjusted age, sex, education, Mok et al).

We also reviewed the evidence for MR-brain imaging features based on non-structural MRI modalities to predict the cognitive outcomes after stroke: the most commonly used modalities were Diffusion Tensor Imaging (DTI), Diffusion Weighted Imaging (DWI) and functional MRI. The evidence was inconclusive as most studies used small sample sizes (n=1-148), combined with a maximal follow-up of 6 months, or focused exclusively on aphasia, which is less relevant to our PICO.

Consensus recommendation

At present, the evidence for prognostic utility in predicting future cognitive decline after stroke is most convincing for white matter lesions.

However, the added predictive value of imaging findings over and above routinely acquired clinical factors remains uncertain.

Further studies of the predictive value of MRI-based imaging variables should use standardized measurements and validated tools.

Consideration needs to be given to the population included, with preferably unselected samples and low rates of attrition from cognitive follow-up.

Results of these studies need appropriate adjustments to distinguish the added prognostic value of MRI imaging features over standard clinical factors such as age, sex and stroke severity.
Despite the importance of post stroke cognitive impairment and dementia we found a marked paucity of high-quality data from RCTs. In some areas, such as pharmacological secondary prevention, there were some, but limited, data, while in other areas, such as cognitive rehabilitation after stroke, there were no data from definitive multi-centre studies. Finally, for some areas, such as the effectiveness of a policy of cognitive screening, there were no trial data at all. This evidence–practice research gap is seen in many areas of dementia work, but seems especially problematic in the field of post-stroke cognitive impairment.[196]

Many high-quality trials have demonstrated that treating cardiovascular risk factors such as hypertension reduces recurrent stroke risk. In view of the known association between stroke and dementia, one might expect such treatments to also reduce future dementia. Lifestyle interventions, medical risk factor modification and cognitive stimulation have all been mentioned as potential preventive strategies after stroke. Our review of the literature suggests that there is no convincing evidence that any of these interventions can prevent cognitive decline or dementia. A similar situation was found for antithrombotic therapy. Of note recent observational data from large population datasets has suggested that treatment of atrial fibrillation with anticoagulation markedly reduced dementia risk, but these results need confirmed in a prospective randomised trial.[197][198]

How intensively cardiovascular risk factors should be treated, particularly blood pressure, has also been debated. Again, there were limited high-quality data from post-stroke dementia to address this question. However, for a non-stroke cohort, the recent SPRINT-MIND study suggested intensive blood pressure lowering to a systolic of 120 mmHg, compared with standard lowering to 140 mmHg, was associated with a reduced incidence of mild cognitive decline and the combined endpoint of MCI and dementia.[199] There has been concern that intensive blood pressure lowering may have risks in people living with extensive small vessel disease and impaired cerebral autoregulation, but the recent PRESERVE study showed no reduction in cerebral blood flow, increased white matter damage, or difference on cognition associated with blood pressure lowering to 125 mmHg compared with 140mmHg.[200] Consistent with this finding, the SP3 cognitive sub-study reported no adverse consequences of lowering blood pressure to this level.[23]

Cognitive performance after stroke differs greatly and identifying participants at increased risk may increase the potential effect of a preventive intervention. Currently, there are no validated instruments to reliably identify those at highest risk of developing poststroke cognitive impairment, although single characteristics including stroke severity, low education and age are associated with a higher risk. Whether high risk individuals can benefit more from interventions aiming to prevent cognitive decline and dementia should be focus of future research. A limitation of preventive strategies in patients with a history of stroke, especially lifestyle interventions, is the high drop-out rate. Improving adherence to these interventions, may contribute to better cognitive outcomes. After stroke, barriers for participating in rehabilitation and in health programs, such as social isolation, depression, and inactivity, are frequently seen. Moreover, these are all risk factors for developing (post-stroke) cognitive decline and dementia.

The evidence around prevention of post-stroke cognitive decline remains imperfect, and unfortunately, the same was true for trials of interventional treatments including cognitive training and medications such as cholinesterase inhibitors. We found few RCTs which investigated cognitive interventions after stroke, included more than 50 participants per group and assessed clinical outcomes over a period of longer than 6 months. We noted an increased amount of research within this area, generating emerging evidence that cognitive rehabilitation, in particular compensatory strategies in the context of individually relevant functional tasks, may be beneficial for people with post-stroke cognitive impairments. However, this evidence has relied primarily on trials with methodological limitations such as inadequate sample size to detect clinically important intervention effects, study designs without control groups, lack of consensus on optimal outcome measures, insufficient treatment dose and lack of long-term follow-up. There is an urgent need for methodologically robust trials on cognitive rehabilitation.

Similarly, we found no robust data that pharmacological interventions including cholinesterase inhibitors and memantine improved symptoms or delayed progression to dementia. There has been debate as to whether effects reported with cholinesterase inhibitors in vascular dementia trials are due to a true effect on vascular dementia, or an effect on concurrent Alzheimer’s pathology. Mixed pathology becomes increasingly common with increasing age. To address this question a randomised controlled trial examined donepezil in a model of pure vascular dementia, CADASIL. Although there was a significant effect on the secondary endpoint of executive dysfunction, there was no improvement in the primary cognitive endpoint or activities of daily living.[126] Therefore we concluded that, in predominantly vascular cognitive impairment, the effect of these drugs is minimal. However, older adults with stroke who have other coexistent neurodegenerative diseases responsive to cholinesterase inhibitors may benefit from a trial of these drugs. Our conclusions with memantine were similar. In contrast, although there was again limited data, we could find no evidence for the use of actovegin and cerebrolysin following stroke and noted concerns around safety and cost.

The first step to effective management of post stroke cognitive impairment is identification of the problem. While some recommend cognitive screening of all suspected stroke admissions in the acute stroke setting, we found no robust evidence to support this approach. We were able to give estimates of the accuracy of various cognitive screening tools, but there were less data for newer tools such as the Oxford Cognitive Screen. Variation in the choice of cognitive assessment is apparent in stroke research and practice. Our data did not suggest a single ‘best’ screening tool for post stroke cognition, and there were few studies that compared differing test strategies. Papers focussed on accuracy metrics, but the choice of tool should also be based on aspects such as feasibility, availability of training and cost.
We evaluated whether multi-item prognostic tools, as well as structural features on CT and/or MRI imaging, obtained in the acute stroke period (days to weeks) were able to contribute to the prediction of dementia and PSCI after 12 months. Multi-item prognostic tools combined variables such as patient demographics, stroke severity, neuropsychological scores and imaging data. We concluded that there is currently a lack of evidence to support the clinical implementation of such tools. Although there is evidence that white matter hyperintensities on both CT and MRI may predict dementia risk, there is insufficient evidence for the routine use of CT or MRI parameters to inform prognosis decision making. This is an area which requires further work. A recent study in 2950 stroke patients found that infarcts in the left frontotemporal lobes, left thalamus, and right parietal lobe were strongly associated with PSCI, and suggested that quantitative mapping of the stroke lesion may provide useful prognostic information. Overall, we encountered numerous issues of sample size, attrition bias, adjustment for covariates and a lack of external validation, which need to be addressed in future studies. In particular, it should be noted that quantification of the severity and location of structural brain imaging abnormalities including atrophy and WMH require the application of visual rating scales by trained observers or at least the application of semi-automated software programs. This limits the clinical utility of imaging variables for dementia prediction in routine clinical practice and highlights the need to determine their independent predictive value over and above other, more easily acquired clinical factors. An additional consideration is how useful prognostic screening for dementia is, in the absence of a specific preventative treatment. However we concluded that it is important to develop robust methods of identifying future dementia risk so that when treatments are available those likely to benefit can be identified.

Post stroke cognitive impairment has been consistently identified as a major area of concern for stroke survivors and their families, and a high priority area for future research. Despite this our comprehensive review identified a paucity of high quality data informing optimal management in this area. Many studies have been small, single centre, and with inadequate control arms. In all areas large adequately powered randomised controlled trials with robust endpoints are required. These need to be multicentre to increase generalisability. We would strongly encourage cognitive endpoints to be added to ongoing secondary prevention trials, adopting a model similar to the addition of cognitive endpoints to the SPRINT-MIND substudy of the SPRINT RCT. Although cognitive issues have not featured as prominetly in stroke Guidelines as may be expected based on their prevalence and importance, there have been some recent publications relevant to the field. The White Paper on cognitive impairment and cerebrovascular disease from ESO complements the content of this Guideline. The White Paper emphasises the need to consider cognitive effects in all people living with stroke and highlights the importance of vascular secondary prevention. The Canadian Stroke Best Practice Recommendations (CSBPR) for mood, cognition and fatigue has a broader remit than our Guideline but covers many similar topics. The CSBPR have more detailed recommendations on many aspects of cognitive rehabilitation and offer guidance on specific rehabilitation strategies. The Australian Stroke Foundation have a ‘living’ Guideline that updates in response to new evidence. This Guideline is not specific to cognition but has sections on assessment and management of cognitive issues across domains of perception, attention, memory, executive function, apraxia and neglect.

Completing large, multi-centre trials in the field of post-stroke cognition is difficult. The lack of evidence to make strong guideline recommendations should not be construed as lack of enthusiasm or lack of will to tackle this problem. We found many examples of pilot or phase II trials with data that were promising but did not meet our pre-specified criteria for inclusion. We have offered suggestions to trialists around design and conduct of trials, but we also make an appeal to research funders to support definitive phase III trials. For clinicians, although we can offer few strong recommendations, we hope our Expert Consensus Statements are helpful. It would be wrong to take a nihilistic view and use the lack of evidence based recommendations in this Guideline as a tool to reduce or remove clinical and research activity in the post stroke cognition space. Quite the opposite, we would hope that this guideline acts as a catalyst to support future research and service development.
